Sense and Sensitivity

Pyrometers for steel furnaces . . . recorders and controls for plastics and brewing . . . sensitive yet robust instruments to maintain the correct temperature and humidity for industrial processes. All are compact, precise, and guaranteed for two years against any defect of materials or workmanship. When the need demands a combination of good sense and highest sensitivity, there is no better value than Negretti & Zambra instruments and controls.

The name that means precision

NEGRETTI & ZAMBRA

Negretti & Zambra Ltd.
Group Offices: Stocklake, Aylesbury, Bucks.

—the vapour diffusion pump for high backing pressures up to 35 torr

"SPEEDIVAC" 2M4A

A four-stage stainless steel mercury vapour diffusion pump, the 2M4A is characterised by its high limiting backing pressure of 35 torr. The ultimate vacuum of 10^{-7} torr (with a mercury vapour trap) and the pumping speed of 70 to 80 litres/sec. can be maintained by a backing pump with a speed as low as 0.1 litres/min. at 35 torr.

With a receiver tank fitted in the backing line the rotary backing pump may be switched off for long periods. This arrangement is ideal both for collecting gas samples and for obtaining complete freedom from noise and vibration.

send for data sheet

"Speedivac" products and service are available internationally.

NEW PURITY STANDARDS

two important biochemicals for clinical determination

BILIRUBIN

Serum Bilirubin determinations in infants suffering from erythroblastosis fetalis have proved an important criteria for the use of exchange transfusions. The accuracy of this measurement has always been open to question because of uncertainty about the purity of bilirubin (1).

Our specifications for Bilirubin are:

(1) Millimolar extinction coefficient of 60.1 ±0.2 in Chloroform at 453 mu.

(2) Complete and rapid solubility at room temperature (for concentration of 6mg/100ml.) in chloroform or 0.2% solution of Na_2CO_3.

The problem of finding an accurate method for bilirubin determination has occupied clinical chemists for 50 years. For determinations of new-born plasma, the most useful procedure is the Lathe and Rutheven (2) modification of the Malloy-Evelyn method (3). Stoner and Weisberg have recently reported an excellent micromethod for bilirubin (4).

For accurate determinations of low values of bilirubin, methods of choice are those of Bruckner (5) and Jendrassik and Grof (6). The methods of Meites and Hogg (7), and Powell (8) have the advantage of rapidity and involve few manipulative steps for the laboratory that does not have access to specialized equipment.

PRICE SCHEDULE:

5 gram bottle	gm.	$14.90
1 gram bottle	gm.	17.90
500 mg. bottle	btl.	10.90

References: (1) R. J. Henry, S. L. Jacobs, N. Chiamori, Clin. Chem. 6, 529, (1960). (2) G. H. Lathe and C. R. J. Rutheven, J. Clin. Pathol. 11, 155, (1958). (3) H. T. Malloy, and K. A. Evelyn, J. Biol. Chem. 119, 481, (1958). (4) R. E. Stoner and H. F. Weisberg, Clin. Chem. 3, 22, (1957). (5) J. Bruckner, Am. J. Clin. Path. 32, 513, (1957). (6) L. Jendrassik and P. Grof, Biochem. Z. 297, 81, (1938). (7) S. Meites and C. F. Hogg, Clin. Chem. 5, 470, (1959). (8) W. N. Powell, Am. J. Clin. Path. Tech. Sect. 8, 55, (1944).

CHOLESTEROL S.C.W.

Cholesterol S.C.W. (standard for clinical work) was developed in our laboratories by the intensive purification of Cholesterol U.S.P. to fill the need for a reliable, pure clinical standard.

Our specifications for Cholesterol S.C.W. are: Molar absorptivity values, Lieberman-Buchard method: 1750 ±30, Sulphuric Acid iron method: 11,500 ±100. To the best of our knowledge, this is the first time that cholesterol of this purity has been available commercially.

When Cholesterol U.S.P. is used as a standard an error of approximately 6% in concentration is introduced, and can run as high as 14% in molar absorptivity. This depends upon the amount of such impurities as cholestanol choles-7-en-3-beta ol, and 7 dehydrocholesterol that are contained in the cholesterol.

PRICE SCHEDULE:

100 grams	gm.	$.80
25 grams	gm.	.90
5 grams	gm.	.95

Of the four Unicam SP.800 models available two are fitted with a special Red-Sensitive photomultiplier detector. In providing these special versions Unicam extend the range out to 850 mμ in the linear wavelength model SP.800B (11,500 cm^{-1} in linear wavenumber model SP.800D) thus further increasing the ability of the SP.800 to meet all requirements.

The Red-Sensitive version of the SP.800 has all the facilities of the standard U.V. instrument including fully automatic source change—the unique second sample position—the beam balance smoothing cam for maximum quantitative accuracy—flat bed recorder—large sample compartment and wide range of accessories. With a total of four models to choose from and overall range of 190—850 mμ (52,500—11,500 cm^{-1}) the new SP.800s are proving the instrument of choice when the requirement is for speedy, reliable analysis.

Write today for the SP.800 booklet or a demonstration. Full information on the SP.800 Sample Compartment will be given in the next advertisement in this series.

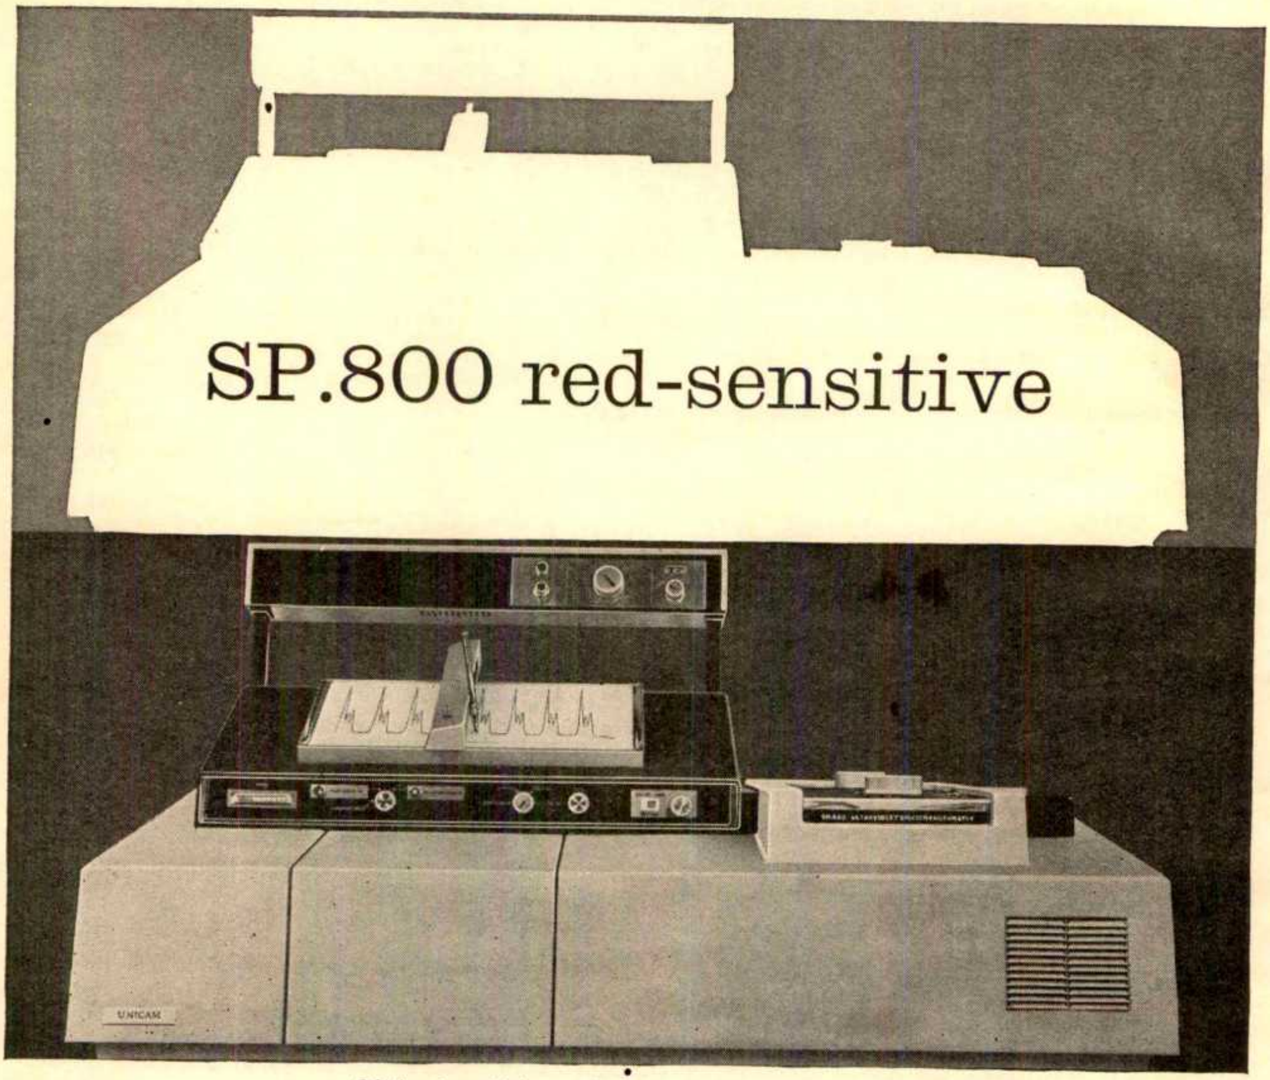
SP. 800 red-sensitive ⬅
large sample compartment
flat bed recorder



Of the four Unicam SP.800 models available two are fitted with a special Red-Sensitive photomultiplier detector. In providing these special versions Unicam extend the range out to 850 mμ in the linear wavelength model SP.800B (11,500 cm^{-1} in linear wavenumber model SP.800D) thus further increasing the ability of the SP.800 to meet all requirements.

The Red-Sensitive version of the SP.800 has all the facilities of the standard U.V. instrument including fully automatic source change—the unique second sample position—the beam balance smoothing cam for maximum quantitative accuracy—flat bed recorder—large sample compartment and wide range of accessories. With a total of four models to choose from and overall range of 190—850 mμ (52,500—11,500 cm^{-1}) the new SP.800s are proving the instrument of choice when the requirement is for speedy, reliable analysis.

Write today for the SP.800 booklet or a demonstration. Full information on the SP.800 Sample Compartment will be given in the next advertisement in this series.

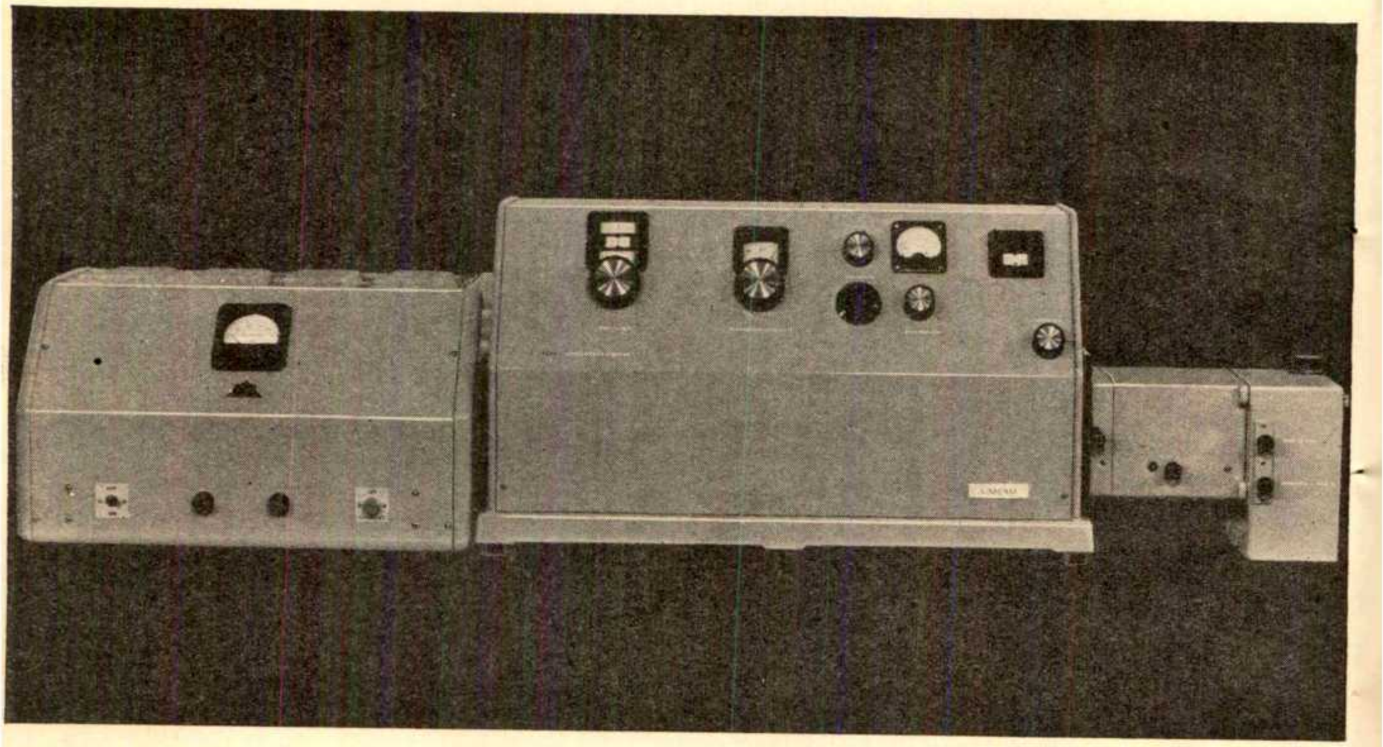
PRECISION ULTRAVIOLET AND VISIBLE SPECTROSCOPY FOR £815



The Unicam SP.500 Ultraviolet and Visible Spectrophotometer is now available complete for mains operation for £815.*

This well tried and proven instrument is to be found in laboratories throughout the world where its accurate reliable performance has set new standards.

With the Unicam SP.500 there are no extras required for normal operation—the price includes everything necessary for precision all mains operation, deuterium 1 amp. supply, 115 D power supply and SP.549 internal power unit—right down to four glass and two silica cells in cases and a set of dust covers. Installation is free. All you provide is your sample.

Write for the SP.500 booklet today.

THE NEW SP.800 ULTRAVIOLET & VISIBLE SPECTROPHOTOMETER

1 chart shift control
2 second sample position
3 beam balance smoothing cam
4 SP.800 red-sensitive models
5 large sample compartment
6 flat bed recorder

The product of all the Unicam U.V. experience and know-how is contained within the new SP.800, the latest Ultraviolet & Visible Recording Spectrophotometer. It is unrivalled for accuracy and yet is extremely simple to operate; it is robust and ideal for routine work.

The wide range of accessories and unique features of the SP.800 make it ideal for organic research, pharmaceutical analysis and quality control, the study of reaction kinetics, general analytical research and every field of analysis and investigation where the requirement is for a low-cost U.V. & Visible Recording Spectrophotometer with maximum versatility.

The SP.800 is available in four models recording in wavelength or wavenumber—with special red-sensitive versions offering a total range of 190-850mμ—52.500–11.500cm^{-1}

For full information on the many outstanding facilities provided by this new concept in modern U.V. instrumentation write today for the SP.800 booklet or a demonstration.

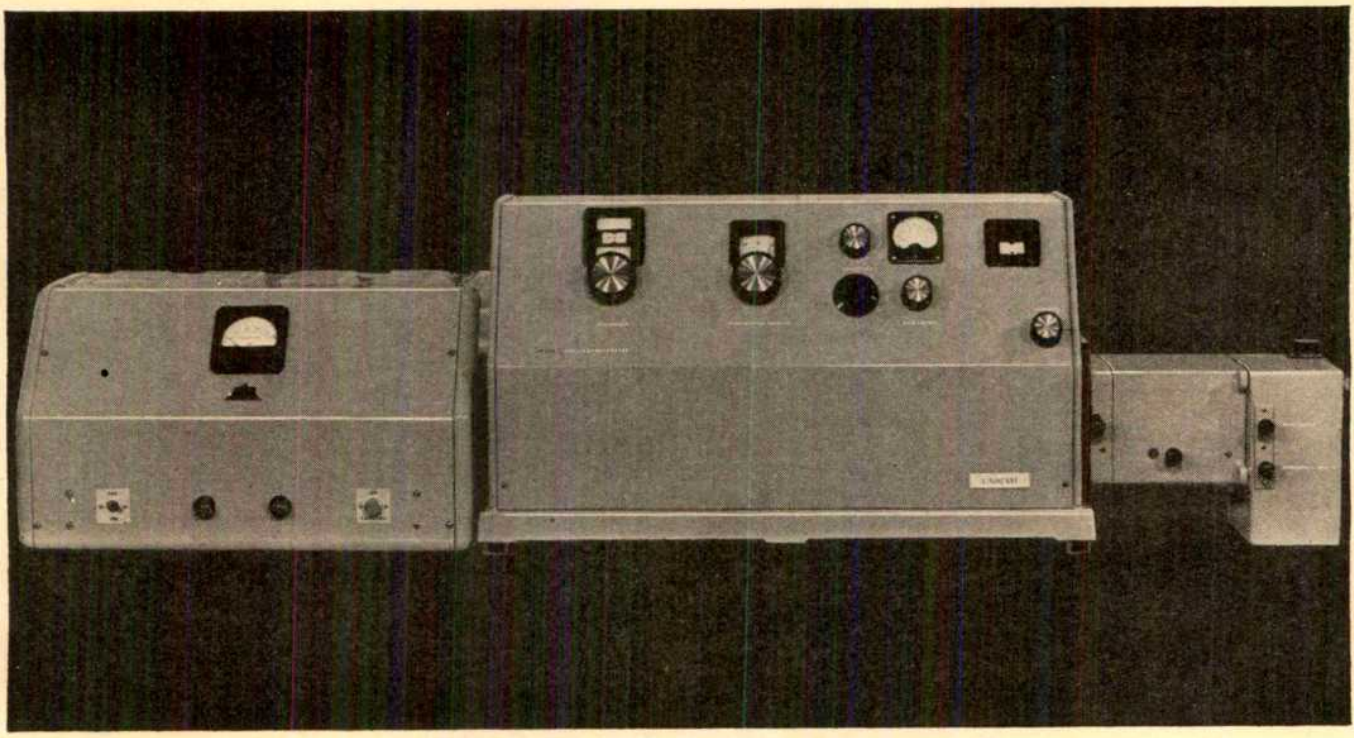
PRECISION ULTRAVIOLET AND VISIBLE SPECTROSCOPY FOR £815



The Unicam SP.500 Ultraviolet and Visible Spectrophotometer is now available complete for mains operation for £815.*

This well tried and proven instrument is to be found in laboratories throughout the world where its accurate reliable performance has set new standards.

With the Unicam SP.500 there are no extras required for normal operation—the price includes everything necessary for precision all mains operation, deuterium 1 amp. supply, 115 D power supply and SP.549 internal power unit—right down to four glass and two silica cells in cases and a set of dust covers. Installation is free. All you provide is your sample.

PROBLEMS OF LEISURE

THE debate in the House of Lords on the problems of leisure on May 13 was recognized to be in direct sequence to the earlier debate on automation on April 8. Although Baroness Burton of Coventry, who opened it, withdrew her motion, the debate essentially developed further some arguments which had been advanced in the earlier debate, and it drew from the Government a reply generally regarded as satisfactory. In spite, however, of the extent to which the two debates were directly related, the second debate covered an even wider field, and its discussion of youth service and the needs of youth was highly relevant to some subsequent incidents of the Whitsuntide week-end. If leisure was seen as an inescapable sequel to the growth of automation, it was recognized that the use of leisure calls for just as much forethought and preparation as the introduction of automation.

Like the Bishop of Coventry in the earlier debate, Baroness Burton emphasized that the two problems were inextricably bound up together, but she added that automation must come at a time of full employment if it was to be acceptable, and that the problem of leisure demanded a completely changed outlook, untrammelled by conventional thinking. Automation and decreasing hours of work made it imperative that the social consequences of increased leisure should receive attention, that people should be helped to use their leisure and provided with the facilities and opportunities for enjoyment. This would mean facing the implications of the inevitable extension of shift working, as well as providing the resources needed, for example, by the Arts Council and the Central Council for Physical Recreation.

The Bishop of Chester reiterated the importance of adequate financial help to the latter Council, the National Playing Fields Association and to other bodies under the Physical Training and Recreation Act, and he did not think that sufficient credit had been given to the Government for what had already been done, particularly since the publication of the report of the Wolfenden Committee on sport. This he was inclined to attribute to an air of improvisation and a lack of continuity in policy; and he thought that there should be an appropriate section in the Department of Education and Science, as well as a Sports Development Council. The challenge to the whole personality which leisure now made could not be met except on the basis of an adequate education in the fullest sense, and this must include the physical as well as cultural and creative activities. The Bishop referred particularly to the need to provide adequately for the needs of the gap between school age and adult-hood noted by the Wolfenden Committee, and also to develop a sense of service such as found expression in voluntary service overseas.

Lord Willis made some reference to the magnitude of the growing demand for recreational facilities, especially for young people. While his suggestion that many of the natural leaders of the youth of to-day had been creamed off in the educational process was later challenged, his sympathetic presentation of the situation of that sector of society included some constructive clues for positive action. We must be concerned with conditions as well as facilities. Legislation for leisure is impossible—unthinkable as well as impracticable—but a scientific revolution calls for a cultural counterpart, and the workers who are trained in new skills for an age of automation must be helped also to find cultural and spiritual development. Lord Willis emphasized that we should start in the schools by arousing interests and stimulating imagination: the service of youth needed overhaul—adequate finance, a big effort to recruit and to train voluntary leaders, and the extension and adequate use of facilities.

Like other speakers, Lord Willis referred appreciatively to the value of such schemes as the Duke of Edinburgh's Award, and he spoke also of the possibilities attending imaginative support of the Arts Council and of the National Theatre, but his final note was the desperate urgency of effective action. Baroness Elliott endorsed much that Lord Willis had said, but thought that the Albemarle Report had led to some improvement in the situation regarding youth leaders; the target of 1,300 new leaders was expected to be reached by 1966, and 142 local education authorities already employed more than 4,000 part-time leaders. She too stressed the urgency of the situation, though she welcomed the increased grants to voluntary organizations by the Department of Education and Science, who had brought in some 38 voluntary organizations since the Albemarle Committee reported. More needed to be done for young adults—she visualized a rather sophisticated and more adult club, with time to talk and to think.

The Bishop of Norwich reminded the House of Lord Bowden's plea for a comprehensive programme of re-education for the nearly 1·5 million of unskilled workers who might well become unemployable if the changes required to maintain the projected growth in our economy were effected. Especially, he stressed the grave possibility of creating and perpetuating large pools of virtually unemployable people; areas of self-perpetuating sub-culture, with all the processes of degeneration built into them. It is this prospect that any educational system which can be regarded as adequate for an industrial society to-day must seek to meet, and the Bishop maintained that this was a vital task of education—to promote interests, a sense of purpose, an enquiring mind and good health—though the home also had its responsibility here. With this, more capital and personal equipment, though not necessarily all, should be provided by the Government for many forms of leisure. In making this suggestion he related the whole debate to the situation revealed in the Newsom Report, *Half Our Future* (*Nature*, 201, 1; 1964). particularly in its chapter "Education in the Slums".

In the conditions described in that chapter, as the Report points out, no adequate education can be given, and the Bishop of Norwich pleaded that it was particularly the children in such areas, and the teenagers in the new housing estates, who should receive first consideration so that they had some chance of fitting properly into a society that professed to value such attributes as orderliness, cleanliness, friendliness, decency and charity. These boys and girls, above all others, needed, as the Newsom Report urged, access to the countryside, the experience of living together in beautiful and civilized surroundings and a chance to respond to the challenge of adventure. They need priority in relation to school journeys, overseas visits and adventure courses. A concern for leisure is a concern for the wholeness and fulfilment of human beings.

It is from that point of view that we can best appreciate the wealth of opportunities for creative thinking, to which Lord Luke referred, offered by the whole problem. He also indicated certain aspects related to the problems of housing generally and also opportunities in which further research might indicate possibilities of greater efficiency and economy with equipment. Baroness Swanborough dealt mainly with the contribution which voluntary service could offer, not simply for growth, but service by youth, particularly to facilitate the participation of youth in voluntary service of all kinds in Britain as well as overseas. The opportunity must be presented with imagination and with some understanding of the conditions under which youth was able to respond, and not simply of the convenience of the voluntary organization itself.

The debate thus covered a wide field, including appropriate reference to the elements of discipline and judgment, and while there were many reservations by other speakers as to the extent of certain developments, it was curious that no one came nearer than the Bishop of Norwich in touching on the argument of Prof. Dennis Gabor's lecture on "Technology, Life and Leisure" to the Royal Institution (*Nature*, 200, 513; 1963), which, like his book *Inventing the Future* (*Nature*, 200, 923; 1963), apart from a reference by Lord Milverton, was also ignored in the earlier debate. The Earl of Bessborough, replying on the debate for the Government, noted that some ten Government departments were interested in the subject and anxious to brief him. Referring to the provision already made, he said that in 1963 the local education authorities provided opportunities for leisure and recreational activities attended by nearly 1·9 million evening students; 1 million had attended evening institutes, and almost 250,000 had enrolled for day-time study in further education establishments. Total expenditure by the Department of Education and Science on adult education in the present financial year was expected to reach about £1 million, apart from the contribution made by the local education authorities and the responsible bodies themselves. On the gap between school and adult life, he said that two-thirds of those in the three age-groups 15–17 were receiving instruction of some kind or another. The possibilities of radio and television in education generally were being examined and he anticipated a definite decision before very long about a wholly educational and experimental channel.

Lord Bessborough also touched on some developments in the public library service and on the support given to the arts through the national museums and galleries, the Arts Council and in other ways—expenditure on which had risen to £11·75 million in 1963–64 from £6·75 million in 1958–59 and was expected to reach £13·5 million in 1964–65. In 1963–64 local education authorities spent £11·25 million on social and physical training under the relevant sections of the 1944 Act, compared with only £6·25 million in 1959–60, nearly half going on the Youth Service. He undertook to ask the Minister to look again at the proposal for a Sports Development Council, and he said that the Minister of Housing and Local Government would like to help the planning authorities to do more to develop recreational facilities in the national parks and to extend the scope of Exchequer grants for that purpose.

It is clear from the debate that the traditional view that education ceases on leaving school or university is already vanishing and that, as Prof. Colin Cherry observed in his lecture "The Scientific Revolution—and Communication" (*Nature*, 200, 308; 1963), education is accepted as a process continuing throughout life. The implications are far from being worked out and account must be taken of them at all stages in our educational system: preparation for leisure, adaptability, cannot be fostered too early, and if curricula are to be very broad and development slower, as Prof. Cherry suggests, examination requirements and entry demands for institutions of higher education must conform with the situation. Education will not make leisure creative, still less meet the needs of the feebler-minded unless it is shaped for the task, and this may call for research, as well as perhaps the use of new tools and techniques.

What could be said of the debate is that it did not focus attention sufficiently sharply on the problem presented by the lowest intelligence group which is threatened most acutely with unemployment as automation extends. This group must, as Prof. Gabor argued, be used for its own good and for the good of society, even if it means some restriction of automation by legislation. That is inescapable, however much we may succeed in fitting the group to enjoy leisure and to make effective use of it.

Probably here more than anywhere else lies the need for creative thought and experiment, and *that* should now be proceeding. Quite apart from the time required to enact any fresh legislation, its initiation by Government is likely to follow rather than precede the recognition by the public of its necessity. Such jobs as those of the dustman, the night watchman, the milkman, the postman and others are unlikely to be protected against automation without some wide public understanding of the situation, and it requires little imagination to visualize the outcry from vested interests which would attend any attempt to give effect to the suggestion of Prof. Gabor that cafeterias and supermarkets should be prohibited. Indeed, even such legal safeguards and prohibitions would not ensure that the posts would be filled by the type of labour in mind without attention to other conditions and a large measure of supporting opinion. What is certain is that automation involves much fresh and constructive thought about its social consequences, and that this should be proceeding as a matter of urgency simultaneously with the technological developments in automation. Only so are either Government or public likely to be ready for action in time to avoid social distress. That could well be also an imperative reason for immediate action to prevent commercial television developing any further obstacles to educational and local broadcasting.

There is a further point made by Prof. Cherry which found an echo in the debate in the House of Lords and which merits elaboration. Reference was made in the debate to the importance of voluntary service, and voluntary service overseas was recognized as providing a valuable outlet for the altruism and idealism of youth. Apart, however, from such satisfactions, the coming of automation is not to be considered entirely as a national affair. There can be no stability if the underdeveloped countries are disregarded. Prof. Cherry referred to the great change in the public conscience wrought by broadcasting and other news services, and to the way in which the great mass of people had now become aware of world conditions, of the increasing disparities and of the mounting political pressures. We cannot fail to consider the needs and position of the underdeveloped countries. he opportunity they offer for disinterested voluntary rvice in many ways and many fields may be no less aportant in its bearing on world stability and co-operaon than on the welfare and fulfilment of the volunteers om Britain who respond to the challenge.

BRAIN MECHANISMS AND MODELS

rogress in Brain Research

ol. 1: Brain Mechanisms. International Colloquium ponsored by the International Brain Research Organizaion (IBRO) on Specific and Unspecific Mechanisms of ensory Motor Integration; Pisa, 1961. Edited by G. Ioruzzi, A. Fessard and H. H. Jasper. Pp. xii+493. 140*s*. ol. 2: Nerve, Brain and Memory Models. Edited by N. Wiener and J. P. Schadé. Pp. viii+280. 80*s*. ol. 3: The Rhinencephalon and Related Structures. Edited by W. Bargmann and J. P. Schadé. Pp. vii+253. 70*s*. (Amsterdam, London and New York: Elsevier Publishing Company, 1963.)

VOLUME 1 of the series *Progress in Brain Research* is the product of a colloquium, sponsored by the International Brain Research Organization (IBRO), on specific and unspecific mechanisms of sensory motor integration. As the colloquium was held in honour of Prof. F. Bremer, it was appropriately concerned with the electrophysiology of the nervous system. There are some two dozen papers. The first is by Sir John Eccles and deals with post-synaptic and pre-synaptic inhibitory actions in the spinal cord. Ragnar Granit writes on recurrent inhibition as a mechanism of control. Among papers of more general interest is one by K.-E. Hagbarth and B. L. Finer on the plasticity of human withdrawal reflexes to noxious skin stimuli in lower limbs. It has been shown electro-myographically that there are two components in the withdrawal reflex—an initial spinal one and another later, probably cerebral. The second can be modified profoundly by hypnotic suggestion, being reduced in amplitude if the subject is told that no pain will be felt, and increased if the contrary is suggested. It was shown to be absent in a patient whose loss of sensibility in the limb was due to hysteria. An investigation by P. Dell shows how the reticular formation which influences alertness and attention is involved in a number of feed-back circuits which tend to maintain it in a state of homeostasis. Alternative sensory pathways and their thalamic integrations are discussed by D. Albe-Fessard and A. Fessard. A. Arduini discusses the tonic discharge of the retina and its central effects, among which is the signalling of the intensity of the steady illumination. The convergence of several sensory modalities on the same cortical neurones is a fact of obvious physiological and probable psychological importance, discussed by R. Jung, H. H. Kornhuber and J. S. Da Fonseca. Among the remaining papers are several on sleep, and the physiological contributions to it made at different levels of the nervous system.

This is mainly a book for specialists; but it provides a broad overall survey of present-day trends in the electrophysiology of the central nervous system, and for the non-specialist there are a few items of considerable general interest.

The development of cybernetics and information theory has provided a temptation to speculate on how the brain might work, which many ingenious minds have found irresistible. Some of the consequences are to be found in Volume 2, which contains the proceedings of a symposium on "Cybernetics of the Nervous System" held at the Royal Dutch Academy of Sciences in 1962. Neurologists, psychiatrists, biologists, engineers, mathematicians and physicists all contributed. There is a paper on the engineering approach to the problem of biological integration by J. D. Cowan from McCulloch's Laboratory at the Massachusetts Institute of Technology. The sequential behaviour of a set of idealized neurones is the subject of P. L. Latour's paper. He investigated nerve nets with mathematical methods similar to those in the theory of linear sequential networks. F. H. George deals with the logical net type representing a sort of idealized or conceptual nervous system. The cybernetic group of the Moscow State University is represented by A. V. Napalkov. P. Müller discusses the characteristics and patterns of learning matrices, and G. W. Zopf the cybernetic significance of the innervation of the accessory motor apparatus of the sensory systems, and the efferent fibres ending on or near the receptor cells. E. Huant approaches the problem of sensory information from the psychiatric point of view, and there are papers concerned with the construction of models explaining some of the parameters of human memory and thinking. G. Pask discusses models of learning and cognition in evolutionary systems and brains, and P. Nayrac puts forward his ideas on the problems of non-linearity in clinical and experimental neurology. Finally, there is a challenging paper by O. D. Wells entitled "Irrelevance of a 'Nervous System'". These are mostly entertaining speculations, and will not become more so until we know more about the finer anatomy and physiology of the neurone.

Volume 3 is a mainly anatomical discussion of the rhinencephalon. F. Valverde writes on fibre degeneration resulting from coagulations in the amygdaloid complex and anterior amygdaloid area, and traces these into three main projecting systems. O. D. Creutzfeldt, F. R. Bell and W. R. Adey investigate the activity of neurones in the amygdala following afferent stimulation, finding that the main input in the anterior area and the basal and cortical nuclei is olfactory, whereas real multi-sensory convergence is the exception.

A. W. Zbronzyna investigates electrical stimulation of the amygdala and shows this to cause autonomic and behavioural effects, which are obtained as components of the defence reaction, and infers the existence of an amygdaloid centre for the defence reaction connected to the integrative centre of this reaction in the hypothalamus. The finer anatomy of the hippocampus is described by T. McLardy and by J. P. Schade and K. Meeter. Other authors discuss the connexions of the olfactory bulb and other anatomical features of the rhinencephalon. The symposium ends with an unresolved debate as to the meaning of this term, A. Brodal wishing to confine it to those structures in the central nervous system which receive fibres from the olfactory bulb. Though by derivation the term rhinencephalon refers directly to the sense of smell, it has come to mean something more for physiologists. In many mammals taste and smell are the primary afferent pathways concerned in feeding and sexual activity, and the parts of the brain in which they terminate are closely linked with pathways which elicit autonomic and emotional responses. Hence to the anatomist the rhinencephalon means one thing, and to the physiologist, another. We may therefore endorse Brodal's concluding suggestion that all who use the term 'rhinencephalon' should put a footnote or make some reference indicating what they mean by it.

BRAIN

RUMFORD REDIVIVUS

Knight of the White Eagle

A Biography of Sir Benjamin Thompson, Count Rumford (1753–1814). By Dr. W. J. Sparrow. Pp. 302+10 plates. (London: Hutchinson and Co. (Publishers), Ltd., 1964.) 50*s*. net.

THIS year marks the one hundred and fiftieth anniversary of the death of Sir Benjamin Thompson Count Rumford, and also sees the publication of the first full-length biography of this remarkable personality which has been written in Britain. This lamentable neglect of "a great man of science, a leader in technology, and a philanthropist of high renown", who inspired the foundation of one of the premier centres of British scientific life, the Royal Institution, is attributed by Dr. Sparrow to the emphasis placed on politics and conflict in the history taught in our schools, and to our national apathy towards the history of science.

In his book, which is an avowed attempt to secure the rehabilitation of Rumford, Dr. Sparrow has set himself three objectives: (1) to tell the story of Rumford's life against the setting of his time; (2) to unravel and exhibit his motives; and (3) to present a balanced account of his scientific work. In pursuit of his aims, Dr. Sparrow, who confesses to an interest in Rumford since his school-days, has during the past twenty years visited all the varied scenes of Rumford's life in both the United States and Europe, and his researches have brought to light a manuscript copy of the journal kept by Rumford on his visit to Munich and Paris in 1801, and an interesting memorandum detailing the younger Boulton's hostile reactions to the Royal Institution. As a result of this dedication to his subject, Dr. Sparrow has been able to compile an authoritative and well-documented account of Rumford's wide-ranging career and manifold activities.

The candid and judicious survey of Rumford's scientific work forms one of the most successful sections of the book. Dr. Sparrow shows clearly that, although Rumford was an 'amateur', in that his scientific work was secondary to his public career, and his strongest motive was not so much scientific curiosity as a passion for order, he was pre-eminent as an apostle of applied science, and outstanding as an experimentalist. Dr. Sparrow admits that Rumford lacked the imagination and mathematical skill of the great theorists, and the compelling curiosity of the greatest experimentalists, but insists that he was far ahead of his time in his advocacy of "the application of science to the common purposes of life", and that his work, while not in the first rank, ensures him a place not far behind the great leaders of science.

Dr. Sparrow traces in careful detail the fascinating story of Benjamin Thompson's rise from a relatively humble origin in America to the eminence of Count of the Holy Roman Empire and Knight of the Order of the White Eagle. His youthful ambiguous behaviour as a Loyalist informer in the American War—his quality as a spy may be gauged from an intelligence report printed in full as an appendix—his escape to England, and his subsequent career as a Junior Minister in Lord North's administration, and later as the right-hand man of the Elector of Bavaria, whose support enabled him to apply his scientific and technological ideas to social ends, are faithfully chronicled with copious references to authorities. But the sober and factual style of Dr. Sparrow's narrative, which is enlivened only by far too infrequent flashes of humour, scarcely evokes that peculiar atmosphere of drama and intrigue which Rumford generated around all his activities. The chapters on the Royal Institution suffer by the omission of an adequate account of the contemporary political and social background, and Rumford's personal reasons for associating himself with the project and later withdrawing from it receive insufficient notice.

It is in his attempt to unravel and exhibit Rumford's motives that Dr. Sparrow is least successful. Admittedly, many details of Rumford's life, linked as it was with such activities as espionage and Freemasonry, are very difficult to ascertain, and Dr. Sparrow resolutely eschews conjecture. He certainly has no illusions about his 'hero', and at times displays a positive distaste for some aspects of his character; at one point he exclaims: "What an unpleasant episode this is" (p. 37), and he hurriedly passes over the details of Rumford's distinctly devious sex-life. But this lack of 'sympathy' with his subject has prevented him from combining into a coherent and convincing whole the many facets of Rumford's complex character. Several crucial decisions in Rumford's career, notably his withdrawal from the Royal Institution in 1802, are reduced to bare statements of fact, such as "He had decided to leave London", instead of emerging as the inevitable result of the interplay of conflicting motives; more than once the reader is left with an impression which is aptly described by a quotation from one of Rumford's own letters: "I cannot help thinking that we are not acquainted with the whole of the secret. There must be something we cannot get at but what that something is I have no conception". But Dr. Sparrow's broad generalization that the two essential clues to Rumford's character are his egotism and his passion for order cannot be questioned.

As a whole, Dr. Sparrow's sound and well-documented study with its comprehensive bibliography and index ably fills an important gap in the library of the history of science, and amply confirms the author's contention that Rumford has for too long been denied his rightful recognition as a great man of science and a leader in technology.

A. H. EWEN

A REASONED VIEW OF SEX

Sex in Society

By Dr. Alex Comfort. Pp. 172. (London: Gerald Duckworth and Co., Ltd., 1963.) 21*s*. net.

SEX in Society, a thoroughly revised version of Dr. Comfort's *Sexual Behaviour in Society*, was first published some fourteen years ago. It will probably be received more favourably than its predecessor because of a much more favourable climate of opinion towards an honest and open examination of the force of sex in our individual and social lives. This does not mean that the reading public has caught up with the author or that his book will be generally acclaimed. Comfort's approach is avowedly anarchistic and, having confounded any religious, humanistic, frustrated and perverted moralists who try to influence public opinion with great conviction and authority on the basis of little substantiated fact, Comfort asks if we really know, for example, whether sexual intercourse can be too frequent, whether masturbation may not be the only suitable alternative to intercourse itself, whether those who give sex instruction and advocate clean-living realize that they probably do more harm than good, and whether strict monogamy is always practicable or even desirable.

In matters of sex the author implies that few Christians live in the twentieth century and most Roman Catholics are still in the sixteenth century, that much English law relating to sex is founded mainly on the prejudices of law-makers, and that many court sentences reflect little but the guilt-complexes of the presiding judges.

Startling as are some of Comfort's views, which are supported by most of the precious few facts available, not many readers would cavil at the reasoned and gentle way in which they are presented. Like all true anarchists Comfort does not expect them to be readily accepted nor to lead to immediate change. What really matters is that a generation has arrived which at long last is prepared to look intelligently and rationally at sex with all its implications for the health of individuals in society. What is also important is that, as genuine sociological investigations get under way, a start may be made to do away with all the feelings of guilt which pervade the sex lives of most civilized peoples.

Although Comfort's book is not free from value-judgments, this clear, sincere and kindly approach to the development of sexual health in individuals and society will stand as one of the outstanding contributions to more dispassionate thinking for many a day to come. It is unfortunate that he can but look through the eyes of a male—this does not explain why Chesser's monumental work on the sexual life and behaviour of British women has apparently been completely ignored. Comfort's book deserves to be followed by one written by an equally enlightened female. Until this occurs, *Sex in Society* could be beneficial reading for all medical, social and legal students, teachers, marriage guidance counsellors, magistrates, judges, and parents. T. H. HAWKINS

WEAK SOURCES OF IONIZING RADIATION

High Sensitivity Counting Techniques

By D. E. Watt and D. Ramsden. (International Series of Monographs on Electronics and Instrumentation, Vol. 20.) Pp. xv+348. (London and New York: Pergamon Press, 1964.) 80*s*. net.

AN increase in the sensitivity of a technique of experimental physics is invariably accompanied by an extension of its range of application. One obvious example is the improvement in the sensitivity of nuclear emulsions which led to the discovery of the π-meson; other examples are to be found throughout the text of *High Sensitivity Counting Techniques*, an account of a special field of nuclear counting. The detection of nuclear radiations is, of course, a rapidly evolving subject, and this book does not attempt to give complete coverage; it is concerned with counters of single particles and with the methods of reduction of the unwanted backgrounds which beset all such instruments. Such a topic might well appear narrow and uninteresting to all but the extreme specialist, but, as the authors point out, the detection of weak activities long known to be important in chronology and in certain problems of nuclear stability has now assumed far wider significance as a result of radioactive tracer work, of the demands of the health physicist and of atmospheric contamination from nuclear explosions. It is the existence of this wider context which has encouraged the authors to place their experience at the disposal of the reader; their interest in the subject was stimulated by S. C. Curran, whose work at Glasgow and at the Atomic Weapons Research Establishment, Aldermaston, has resulted in many of the techniques described in the book.

There is, throughout this volume, an emphasis that high sensitivity in a counter is not necessarily the same as low background, but since the latter reacts favourably on the former, it turns out that most of the book is devoted to the background problem. The origins of counter background are analysed at the outset and the significance of the cosmic ray processes of neutron production and electromagnetic cascade are described. This leads on to the empirical science of shielding and much attention is rightly directed to the anti-coincidence ring of counters with which it is almost essential to surround a low-level counter. This is a recurrent theme throughout the book. There follows a section on the construction of the counter, in which selection of materials for both counter and shield is of prime importance; there is the implication that materials prepared before the age of fission may have to be reserved for the counter-maker of the future. The radiation shield may, in many cases, be elaborate and expensive and there is mention of the construction of special laboratories in which many different low-background counters may be used or tested. Such laboratories share with the anechoic chamber a somewhat eerie quality; in one the heartbeats of a visitor are heard, in the other his content of potassium-40 and cæsium-137 is displayed.

The central chapters of the book deal with the detection of low levels of α- and β-activity. The former problem is simplified by the high ionizing power and short range of the particle; there are surveys of phosphors, gas-filled counters and semi-conductor counters from a practical point of view. The chapter on carbon-14 dating deals with the most widely known of all the applications of low-level counting, and perhaps the most tangible, since the range of times involved is commensurate with recorded history. The nucleide carbon-14 is also used in many tracer investigations, but it is apparently giving way to tritium (^{3}H), which is detected most elegantly and efficiently in a gaseous proportional counter. This latter technique and similar techniques for low-energy β-emitters such as sulphur-35 (and also X-ray and γ-ray sources) are explored in a separate chapter. The limitation arising from the low vapour pressures of many otherwise suitable compounds is mentioned and a high-temperature counter to overcome this is described. The nuclear physicist will recognize the importance of this topic in the investigation of K to L conversion electron ratios in radiative transitions, and of electron-capture to positron ratios in β-decay.

A later chapter is devoted to the more generally applicable techniques of radioactivity; this is largely a description of different counters and of the variants of the anti-coincidence ring; it contains a useful survey of source preparation and of the corrections for scattering and absorption in activity determinations. For the detection of higher energy γ-radiation, the sodium iodide crystal is still pre-eminent, although it is being challenged by the bulk conduction counter (not mentioned in this book). The high-sensitivity aspects of this subject are illustrated by accounts of determination of the lifetime of vanadium-50 and lutetium-176; again screening is of outstanding importance. Finally, a chapter is devoted to whole-body monitoring, a subject the technology of which is rapidly developing. Since 'patient psychology' is involved, high-sensitivity counters are necessary to obtain quick results.

Messrs. Watt and Ramsden have patiently covered a wide field of enterprise. As a result, this book is heavy with factual detail; but while this makes it unsuitable for the general reader, it commends it to the user, be he physicist, biologist, or Civil Defence officer. As a volume in a monograph series, the work is suitably placed; it should be available as a hand-book in every laboratory in which precision techniques of nuclear counting are used. W. E. BURCHAM

THE NORTH AMERICAN LANDSCAPE

Face of North America

The Natural History of a Continent. By Peter Farb. Pp. xv+316. (London: Constable and Co., Ltd., 1963.) 45*s*.

THE author of this admirable book is somewhat of a Gilbert White—but his parish is a continent, and he has supplemented his own far-flung observations of its natural history by information gleaned from "those dedicated custodians of the landscape—the employees of the National Park Service, Forest Service, and National Wildlife Refuge System, and their Canadian counterparts". The result is a popular monograph in the grand manner, written with a fine command of language and a pleasing simplicity of style, which happily combines within its covers the literary requirements of a best-seller and the factual accuracy of a serious work of science. His theme is the inter-dependence of all realms of natural history—the rocks, water, soils and the plant and animal kingdoms; and he develops this topic for all the great topographical divisions of North America, from the barrens of the Canadian arctic to the swamps of the Mississippi delta, from the submergent coast-line of New England to the wave-sculptured headlands of the Pacific shores. A recurrent motif in this scenic symphony is that of evolutionary change resulting from gradual desiccation since the Great Ice Age.

In the first section of his book, Mr. Farb briefly outlines in layman's language the geological processes which have sculptured the surface of the land. Thence he proceeds to explain the forces that have shaped the coasts of the continent, with intimate accounts of some of the more interesting fauna which inhabit these shores. Similar chapters relating physiography and ecology follow on rivers and waterfalls, on lakes and bogs, on hot springs, geysers and caves, on the mountain systems and on the Great Divide. He is at his best in describing the forests—the primeval forests of the Great Smoky Mountains, the redwoods and the giant sequoias of the Pacific Coast. Chapters on "The Drylands" deal with the grassland zones, the Colorado Plateau, and the various sections of the Great American Desert, each main part of the Desert having its characteristic indicator plants—the Joshua tree of the Mohave, the saguaro cactus of the Sonoran, the agave of the Chihuahuan and the sagebrush of the Great Basin. A 36-page appendix lists, with descriptive notes, all the national parks and monuments, national forests, wild-life refuges and other sanctuaries in the United States and Canada; and the book concludes with a well-chosen bibliography.

The depredations of man, Indian and European alike, are duly censured; but the picture painted is less gloomy than some depicted elsewhere. One reads that to-day there are more deer, more moose and more song-birds than when Columbus arrived. Thanks to the National Audubon Society, "the American egret, roseate spoonbill, whooping crane, flamingo and half a dozen other notable species have made the long flight back from near-extinction". "Several decades ago the bison, the elk, the pronghorn, the beaver, the sea otter and many other mammals appeared doomed as species; they are no longer in deep peril to-day."

None of the many excellent illustrations in the volume is in colour—a deficiency which will be deplored by those acquainted with *Arizona Highways* and comparable travel literature—but this is doubtless unavoidable in a work otherwise handsomely produced at a low cost. To the student proposing to emigrate westward, Mr. Farb's book should be obligatory reading. In those fortunate enough to have toured the North American continent it will evoke many pleasing memories. C. F. Davidson

INSPIRATION OF THE MIDLANDS

The Lunar Society of Birmingham

A Social History of Provincial Science and Industry in Eighteenth-Century England. By Robert E. Schofield. Pp. x+491+12 plates. (Oxford: Clarendon Press; London: Oxford University Press, 1963.) 70*s.* net.

Mr. SCHOFIELD, who has in earlier papers analysed the membership of the Lunar Society of Birmingham and the relations between the Society and the Society of Arts, now gives us in this full-scale study of the Society and its members a notable and scholarly contribution to the study of the interactions of science and technology in the late eighteenth century. This is probably the major interest of the book to-day rather than its contribution to the social history of provincial science and industry, which the sub-title suggests. Systematically and thoroughly, Mr. Schofield describes the background in which the Lunar Society arose, the character of the Lunar Circle out of which it was, though still informally, founded, the founding of the Society and its activities in the decade in which it fully flourished, and finally the circumstances which led to its decline and end.

All this is done with a wealth of scholarly detail and precision of reference that must impress the most casual reader with some sense of the immense pains that have gone to the collection of facts so widely scattered, for formal records of the proceedings of this Society do not exist. Much of the material displays the personal qualities and activities of its individual members and their friends—of Small, Wedgwood, Edgeworth, Whitehurst, Watt, Withering, Keir, Boulton, Priestley, Darwin, Day and, finally, Galton, Stokes and Johnson. Here, in so far as it illuminates their relations, the book is fairly described as a contribution on the social history of the times. However, to write this is likely to provoke the comment that there is remarkably little indication of the attitude of manufacturers to the working conditions of their factories, or that, from another angle, we are told too little of Boulton or Wedgwood, for example, as business men. The emphasis is perhaps a little too much on the side of science, insufficiently so on the industrial society.

That seems to be one weakness in the book, for the outstanding feature of the Lunar Society was the way in which it appears to have enlisted the interest of all its members in the discussion and examination of whatever problems were brought to their notice by any one member. At its peak the Society was a remarkable demonstration of the value of discussion by a group of men who could bring to bear on the subject discussed a wide range of outlooks, experience and technique. The Society is of great interest from the point of view of the interaction of science and technology and industry in the late eighteenth century, but in this as in later periods there are still many gaps in our knowledge.

There is one other weakness and that where it might have been hoped the book would make an important contribution. An impressive feature of the Lunar Society is the extent of its links with the Royal Society and with the Society of Arts. Eleven of its members were members of the former and eight of the latter Society: they read papers to them and were able to draw freely on the experience and knowledge to be found among their fellow members. These links are important, and there were other links with local societies—societies which continued long after the Lunar Society ended; for example, the Literary and Philosophical Societies of Manchester and of Newcastle upon Tyne, and the Derby Philosophical Society. Mr. Schofield notes these links, but when in conclusion he discusses "Lunar Descent and Lunar Influence" he has little to add on this aspect, which is far more important than the biographical aspect on which his discussion centres. There are features of the Lunar Society which reappear in the Manchester Literary and Philosophical Society and in the Whalley meetings started by Lyon Playfair about 1843. Both groups included several Fellows of the Royal Society, and some connexion may well exist between the latter meetings and the Chemical Section of the Manchester Society established by the versatile James Young some time after 1839. The exploration of all these links might well be rewarding and throw some light on the development of dyeing and calico printing in the area, and, only a few years later, on the rise of the dyestuffs industry there. Reports prepared for contemporary meetings of the British Association in Manchester and in Newcastle, for example, point to the existence of a lively intermingling of science and technology, with movement from one to the other as well as free discussion.

When all due allowance is made for such shortcomings, this is a welcome and scholarly tribute to a Society the place of which in our industrial and scientific history should not be forgotten. It is a reminder, too, at a time when men are liable to be obsessed with mechanical contrivances in communication and to be separated by over-specialization, of the value of personal contacts and discussion across the different disciplines. The significance of the Lunar Society for innovation and creative advance may well become even clearer if Mr. Schofield's labours induce others to follow his example and patiently strive to fill in some of the further gaps in our knowledge of subsequent interactions of science and technology to which passing reference has here been made.

R. Brightman

ALLOCATION OF FREQUENCIES FOR RADIO ASTRONOMY AND SPACE SCIENCE*

By Dr. R. L. SMITH-ROSE, C.B.E.

Past-President, International Scientific Radio Union, and Secretary-General, Inter-Union Commission on Frequency Allocations for Radio Astronomy and Space Science

DURING the past few years the subjects of radio astronomy and space science have required serious consideration on the part of those, both national and international, organizations responsible for allocating the available spectrum of radio frequencies among the numerous services—including communications, navigation and broadcasting—using radio waves. The present Radio Regulations drawn up by the International Telecommunication Union in 1959 recognize that the radio astronomy service is unique in that it is based solely on the reception of radio waves of cosmic origin. It does not itself originate any radio waves and therefore causes no interference to any other service. It does, however, require to be protected from interference caused by the operation of transmitters in any of these other services, particularly since the radio astronomer has developed receiving techniques of the highest sensitivity.

On the other hand, for the conduct of space research with the aid of unmanned Earth satellites, it is essential to have the use of a number of radio frequencies for transmission and reception. In the first place, once the satellite with its load of instruments has left the launching vehicle, any subsequent and not pre-determined changes to its orbit or flight path must depend on radio control from the ground station. Secondly, radio direction finding and tracking techniques are necessary to determine the position of the satellite throughout its flight. Thirdly, the information collected by the measuring instruments carried in the satellite is, in most cases, transmitted by radio to the observer, either continuously or on command at intervals during the flight.

The frequencies selected for these purposes must be both suitable for transmission over the path from satellite to ground, and selected so as to cause the minimum disturbance to all other services using radio communication. Although general research into the generation and reception of radio waves has been steadily extending the spectrum of frequencies available for practical use, there has also been a corresponding increase in the demand for frequencies by all the other services throughout the world. To avoid what might easily become a state of confusion—and even chaos—in the radio field, international conferences are organized at intervals to discuss, and resolve so far as possible, the technical and administrative problems involved. Since radio astronomers and space scientists are among the latest applicants for the use of portions of the radio frequency spectrum, it will be useful to describe briefly the international organizations concerned with this subject and the manner in which they operate.

International Telecommunication Union

In the early years of the present century it became clear that the new and rapidly developing service of radio communication would need protection at both national and international levels, and rules drawn up to control its use. After various conferences held at intervals of a few years from 1906 onwards, the International Telecommunication Union (ITU) was formed, and later became one of the specialized agencies of the United Nations. The Union has a permanent secretariat in Geneva, Switzerland, together with a specialized staff to deal with technical problems associated with line and radio communications, respectively.

At the Atlantic City Conference of the Union held in 1947, steps were taken to record all frequencies in use by radio stations throughout the world; and a Frequency Allocation Table was drawn up to cover all services then in operation. This Table was used as the basis of negotiation as developments took place in the radio field, and the various new, as well as the existing, services were seeking frequencies for their use.

To assist the ITU in its work, the International Radio Consultative Committee (CCIR) was established in 1927 for the purpose of investigating technical questions of interest to international radio communications. These questions include the technical development of sending and receiving equipment, the propagation of radio waves of all frequencies and under all practical conditions of use, and the interference arising from both natural and man-made disturbances. The Committee also deals with the specification of conditions and tolerances appropriate to all applications of radio. The function of the CCIR is limited to advising the ITU on the various technical problems associated with all the applications of radio, with the object of ensuring that the radio frequency spectrum is divided among the users in the most economical and efficient manner possible; and so facilitate the conduct of the individual services with the minimum of mutual interference.

In 1947, the portion of the radio spectrum in which frequencies were allocated was limited to the range 10 kc/s–10,500 Mc/s (or 10·5 Gc/s). At the next full Administrative Radio Conference held at Geneva in 1959, the range of frequencies covered in the Allocation Table was 10 kc/s–40 Gc/s (corresponding to wave-lengths from 30 km–7·5 mm). The increase was due to the major developments which had occurred in the intervening twelve years in such fields as communication by ionospheric and tropospheric scatter, navigation and surveying techniques, and for scientific research in radio astronomy and the exploration of space. For the first time, the Geneva (1959) conference recognized and defined the Radio Astronomy Service, and also envisaged and made provision for the possibility of radio waves being required for communication with, and control of, man-made vehicles travelling both within and outside the Earth's atmosphere.

International Council of Scientific Unions

Concurrently with these developments in the field of practical radio communications, the International Council of Scientific Unions (ICSU) appreciated the need for advanced and co-operative scientific research in space to increase our general knowledge of the Earth's environment and to provide a basis on which various future expeditions in space could be founded.

As a member body of ICSU, the International Scientific Radio Union (URSI) has since its formation in 1913 been actively engaged in organizing and conducting scientific research in radio throughout the world: and it has encouraged the application of radio measuring techniques to the study of the Earth and its atmosphere, and the influence of the Sun's radiation on the latter. On the practical side, URSI has collaborated very closely with CCIR on many problems of mutual interest; and in recent years these have included communication with, and location of, man-made vehicles in space.

---

* Substance of a paper presented at the Seventh Plenary Meeting of the International Committee on Space Research (COSPAR), held in Florence during May 8–20, 1964.

But there are two other member bodies of ICSU very interested in the problems of the use of radio techniques in association with outer space. One of these—the International Astronomical Union (IAU)—is among the oldest of the scientific unions; and it is very much concerned nowadays with the use of radio, as well as light, waves for modern astronomy. Apart from the use of radio for rapid communication between observatories, astronomers have for many years been engaged in an investigation of the relationship between time derived from astronomical observations and that provided by physicists from the atomic frequency standards. The introduction and development of radio receiving techniques to an extremely high degree of sensitivity in radio astronomy has opened up new vistas in our universe which could not be explored by optical techniques alone.

The other, and youngest, member of ICSU is the International Committee on Space Research (COSPAR). Its great and healthy activity is indicated by the fact that, since its formation some five years ago, it has already held five international symposia, the first being in Nice in January 1960, and the fifth has recently been held in Florence, May 1964. The scope of these symposia provides for discussion on a wide international basis of all scientific problems associated with the Earth's atmosphere and outer space, and the radiations and other phenomena which determine the physical conditions associated with the solar system. It is for the direct assistance of all this research in space science that the allocation and protection from interference of a number of suitable bands of radio frequencies is of paramount importance.

Inter-Union Commission on Frequency Allocations for Radio Astronomy and Space Science (IUCAF)

It was at the General Assembly of URSI in London in September 1960 that the subject of frequency allocations for radio research was discussed by the interested commissions of the Union. Afterwards, at an informal meeting of representatives of URSI, IAU and COSPAR, a proposal was formulated to constitute an Inter-Union Commission which should first co-ordinate the future requirements of frequency channels for radio astronomy and space science; and then take appropriate action on behalf of the three constituent bodies to bring suitable proposals before the ITU with the view of securing frequency allocations to meet these requirements. These proposals were afterwards approved by the member bodies of the Commission and endorsed by the Executive Board of ICSU at its meeting in Lisbon in October 1960. The constitution and terms of reference of the Commission have been published elsewhere[1].

While a great deal of the work has been conducted by correspondence, four full meetings of the Commission have been held between October 1961 and May 1963. During this period the activities of the Commission were formally recognized by the ITU, and its representatives participated in both Study Group meetings and in the 1963 Plenary Assembly of the CCIR, at which the technical issues involved in space science and communications were discussed on an international scale. It was following this assembly of CCIR, supported by other representations, that the Administrative Council of the ITU agreed to include Radio Astronomy within the terms of reference of the 1963 Extraordinary Administrative Radio Conference. As a consequence of this action, the IUCAF, with its constituent member bodies, URSI, IAU and COSPAR, was an active participant in the Conference and was able to press through National Administrations for a number of bands of frequencies to be allocated to both radio astronomy and space research, and for the improved protection of these bands from interference by other radio services.

The Extraordinary Administrative Radio Conference (EARC) was held in Geneva during October 7–November 8, 1963. It was attended by more than 350 representatives of 74 National Administrations, and of other interested international organizations. While the main objective of the Conference was to allocate frequency bands for space radio communication purposes, it also dealt with frequencies for space research and radio astronomy[2].

Radio Astronomy

In the publications of the ITU there are now three definitions relating to radio astronomy, as follows: (1) *Radio Astronomy*, astronomy based on the reception of waves of cosmic origin; (2) *Radio Astronomy Service*, a service involving the use of radio astronomy; (3) *Radio Astronomy Station*, a station in the radio astronomy service.

It is to be noted that the Radio Astronomy Service differs from all other radio services in two important respects: (*a*) it does not itself originate any radio waves, and therefore causes no interference to any other service; (*b*) a large proportion of its operation is conducted by the use of reception techniques which are several orders of magnitude more sensitive than those used by other radio services.

Table 1 gives brief details of the twenty bands of frequencies now allocated to the radio astronomy service. In some cases, the allocated frequencies are shared with other services with recommendations that every effort should be made to avoid interference. But it is to be noted that the band 1,400–1,427 Mc/s covering the natural radiation of the hydrogen line is now allocated on a world-wide exclusive basis with no reservations. It was also very opportune and timely that, during the Geneva Conference, the United States delegation was able to announce the identification of two absorption lines—at 1,665 and 1,667 Mc/s—in the radio spectrum of Cassiopeia *A*, due to the presence of the OH radicle[3]. A suitable note has been incorporated in Table 1.

Attention is directed to Annex 12 of the ITU document[2] entitled "Notices Relating to Stations in the Space and Radio Astronomy Services". Section *F* of this Annex describes the "Basic Characteristics to be Furnished in Notices relating to Frequencies to be Received by Radio Astronomy Stations". A suitable tabular form of presentation of these characteristics is illustrated, and this shows that the information sought comprises: the name of the station or observatory; its geographical coordinates and altitude; the central frequency and the width of the frequency band observed; the antenna characteristics and noise temperature; the maximum hours of reception and the class of observation pursued.

It is considered to be in the interests of radio astronomers that they should: (1) supply to their national administrations as much of this information as possible, together with any other relevant details; (2) so far as practicable, concentrate their observations in the frequency bands now allocated for their use as shown in Table 1.

The footnote references relate to the ITU document[2], which should be consulted for their interpretation and for further details of the conditions which apply to the various frequency allocations.

Finally, a recommendation adopted by the EARC provides that: (1) the next Ordinary Administrative Conference should give further consideration to the pro-

20	36·5–37·5			Footnote 412 *E*		

vision of improved frequency allocations for radio astronomy; (2) in the meantime, administrations should afford all practicable protection to the frequencies now allocated to radio astronomy on a shared basis with other services.

Frequencies for Space Research

The need of the space research scientist for protection of radio frequencies is somewhat different from that of the radio astronomer. While a number of satellites are already in use for direct application to the extension of world-wide radio communications, others are placed in orbit around the Earth or farther afield with the object of extending our knowledge of the upper atmosphere at increasingly greater heights, and of measuring various physical quantities in outer space. In some cases, the frequencies required are for the control of instruments in the satellite or for locating it during its orbit; and here, in some instances, the frequencies can be conveniently shared with the corresponding requirements of, say, communications satellites. But, bearing in mind the inaccessibility of the scientific equipment carried in the space vehicle, and the need to use the measuring apparatus for the maximum proportion of the available time, it is important to ensure that the results of the scientific measurements can be communicated to the ground controlling station or laboratory with the minimum of delay or interference. It is thus desirable that a number of bands of frequencies in appropriate parts of the spectrum should be allocated, without danger of interference, to the needs of scientific research being conducted with the aid of satellites in orbit.

In the Radio Regulations, Geneva 1959, four definitions referred to radio communication services between space stations or between Earth stations and space stations. These are:

No. 70. *Space Service*. A radio communication service between space stations.

No. 71. *Earth–Space Service*. A radio communication service between Earth stations and space stations.

Table 2. Review of Frequencies allocated to Space Research in the "Final Acts of the Extraordinary Administrative Radio Conference", Geneva, 1963

No.	Frequency band (Mc/s)	Allocations in ITU Radio Regulations: Geneva, 1959		Revised allocations, Geneva, 1963, region:		
		Applicable to regions	*Rec.* = Recommendation *F* = Footnote	1	2	3
1	10·003–10·005	1, 2 and 3	*F* 215 †	No change, except the modification of footnotes 215, 221 and 235		
2	19·990–20·010	1, 2 and 3	*F* 221			
3	39·986–40·002	1, 2 and 3	*F* 235			
4	15·762–15·768	No allocation		Secondary allocation (primary in some countries—see *F* 215*A*). Fixed services as primary		
5	18·030–18·036					
6	30·005–30·010	No allocation		Primary allocation, with fixed, mobile and space (satellite identification) also as primary		
7	136–137	1, 2 and 3	Primary service *F* 280	Primary (T and T)*, with fixed and mobile also primary: *F* 281*A* (and recommendation No. 7*A*)	Primary (T and T) and exclusive subject to *F* 281*B*. *F* 281 (and recommendation No. 7*A*)	Primary (T and T) with fixed and mobile also primary: *F* 281*A* (and recommendation No. 7*A*)
8	137–138	No allocation		*(T and T) primary, with meteorological satellite, and space also primary: various footnotes relate to use of this band for other services in some countries. *F* 281*F*		
9	143·6–143·65	No allocation		Primary (T and T), shared with other primary services		
10	183·1–184·1	1, 2 and 3	*F* 294	Secondary allocation in accordance with *F* 294 modified		
11	400·05–401	1, 2 and 3	Primary service *F* 280	Primary (T and T) shared with meteorological aids and meteorological satellite (maintenance telemetering) as primaries		
12	900–960	No allocation		*F* 339*A* specific portions of the band may be used on a secondary basis		
13	1,427–1,429	1, 2 and 3	Primary *F* 280	Assigned to space (telecommand), not research		
14	1,700–1,710	1, 2 and 3	Secondary *F* 280	Primary (T and T) with fixed (primary) and mobile (secondary)	Primary (T and T) exclusive except in Cuba	Primary (T and T) with fixed and mobile also primary
15	2,110–2,120	No allocation		*F* 356 *A* may be used for telecommand in deep space research subject to international co-ordination		
16	2,290–2,300	1, 2 and 3	Secondary *F* 280	Primary (T and T) in deep space) with fixed (primary) and mobile (secondary) *F* 356*C*	Primary (T and T in deep space), exclusive except in Cuba	Primary (T and T in deep space) with fixed and mobile also primary
17	5,250–5,255	1, 2 and 3	Secondary *F* 280	Secondary service, shared with radiolocation as primary		
18	5,670–5,725	No allocation		Secondary service (deep space research), with radiolocation (primary) and amateur (secondary). Primary in some countries (*F* 389*A*)		
19	8,400–8,500	1, 2 and 3	Secondary *F* 280	Primary, with fixed and mobile also primary, subject to *F* 394 *A* and *D*	Primary, exclusive except in Cuba	Primary, with fixed and mobile also primary, subject to *F* 394 *A* and *D*

24	34·2–35·2	No allocation		Secondary (primary in some countries, *F* 412*C*), with radiolocation as primary		

F = footnote reference: the ITU document should be consulted for interpretation of the various footnotes. * T and T = telemetering and tracking.

No. 72. *Space Station.* A station in the Earth–space service or the space service located on an object which is beyond, or intended to go beyond, the major portion of the Earth's atmosphere and which is not intended for flight between points on the Earth's surface.

No. 73. *Earth Station.* A station in the Earth–space service located either on the Earth's surface or on an object which is limited to flight between points on the Earth's surface.

At the EARC, Geneva 1963, some thirty new definitions were drawn up in relation to 'Space Systems, Services and Stations' and 'Space, Orbits and Types of Objects in Space'. From these may be quoted the following terms and definitions relating to space research.

No. 84 *AM*. *Space Research Service.* A space service in which spacecraft or other objects in space are used for scientific or technological research purposes.

No. 84 *AN*. *Space Research Earth Station.* An Earth station in the space research service.

No. 84 *AO*. *Space Research Space Station.* A space station in the space research service.

No. 84 *AW*. *Space Telemetering.* The use of telemetering for the transmission from a space station of results of measurements made in a spacecraft, including those relating to the functioning of the spacecraft.

No. 84 *AY*. *Space Telecommand.* The use of radio communication for the transmission of signals to a space station to initiate, modify or terminate functions of the equipment on a space object, including the space station.

No. 84 *AZ. Space Tracking.* Determination of the orbit, velocity or instantaneous position of an object in space by means of radiodetermination, excluding primary radar, for the purpose of following the movement of the object.

No. 84 *BA. Deep Space.* Space at distances from the Earth equal to or greater than the distance between the Earth and the Moon.

No. 84 *BH. Spacecraft.* Any type of space-vehicle, including an Earth satellite or a deep-space probe, whether manned or unmanned.

It will be recalled that the main purpose of this EARC was "to allocate frequency bands for space radio communication purposes". During its deliberations, however, the Conference gave full consideration to the need for frequency allocations for space research in addition to those required for communications by means of satellites and for control, meteorological and navigational purposes. While it may not always be necessary to assign separate bands of frequencies for the tracking and reception of data from research satellites as distinct from those used for radio communications, the frequencies now assigned to the space research services are listed in the appended Table 2.

In order to take account of the new conditions resulting from the development of space communications for both practical applications and research purposes, appropriate additional sections were drawn up at the 1963 Conference to Article 7 entitled "Special Rules relating to Particular Services" of the 1959 Radio Regulations. These additions include recommendations as to the choice of sites, frequencies and power limits for Earth stations in the space service, and the use of appropriate devices for terminating radio emissions from space stations when necessary.

In conclusion, attention is directed to the fact already mentioned above that the revised Radio Regulations of the ITU will provide for the notification and recording of frequency assignments to stations in the Space and Radio Astronomy services for inclusion in the Master International Frequency Register. For both Earth and space stations in the Space Research Service, the technical details required include the frequency, power, class of emission and identification signals used for the various purposes of telemetering, tracking, telecommand and transmission of research and other information. Additional orbital information is sought in the case of an Earth satellite; and for a space probe a general indication of its trajectory should be provided. Specimen tables are given in the "Final Acts" of the 1963 Geneva conference indicating in detail the information it is desirable to provide[2].

Table 2 gives details of the bands of frequencies allocated to space research, first in the existing Radio Regulations of the ITU, Geneva, 1959; and secondly, the revised allocations resulting from the Extraordinary Administrative Radio Conference, Geneva, 1963. As was also the case in Table 1, for the purpose of frequency allocations the world has been subdivided into three regions, which are defined in detail in the existing Radio Regulations, 1959. In very broad terms Region 1 incorporates Europe and Africa, but includes all Turkey and the U.S.S.R. if outside these continents; Region 2 comprises the Americas and Greenland; while Region 3 covers the rest of the world, mainly Asia, Australia and New Zealand.

JODRELL BANK *Mark II* RADIO TELESCOPE

By Sir BERNARD LOVELL, O.B.E., F.R.S.

University of Manchester, Nuffield Radio Astronomy Laboratories, Jodrell Bank

SEVEN years ago a description was given in *Nature*[1] of the radio telescope at Jodrell Bank which was then nearing completion. This *Mark I* instrument with its 250-ft. aperture paraboloidal bowl has been popularly associated with *Sputniks* and space probes; but, in fact, 96 per cent of the 30,000 h of research carried out with the telescope have been concerned either with the study of the galactic and extragalactic radio emissions or with radar investigations of the solar system.

The fundamental design characteristics of this telescope were laid down in 1949–51 when there seemed little prospect of effective studies of the radio emission on wave-lengths in the centimetre region. Consequently, the aim was to make a fully steerable telescope as large as possible for work in the metre wave-band. Originally we had a wave-length of about 1 m in mind for the lower working limit, but in practice the instrument has been much used on wave-lengths down to 50 cm, where its performance is still close to the theoretical value. Indeed, important observations (including the only measurement so far made of the interstellar magnetic field[2]) have been carried out on the neutral hydrogen line wave-length of 21 cm. The performance falls off rapidly at shorter wave-lengths, and the telescope cannot be used in the 10-cm band, since neither the bowl profile nor the control system is sufficiently accurate at these short wave-lengths.

Some years ago it became clear that observations in the centimetre range would be essential to a full understanding of the processes of emission of the galactic and extragalactic radio waves, and moreover, the development of low noise maser and parametric amplifiers opened up the possibility of important research work in that region. Application to the Department of Scientific and Industrial Research for a grant to build a large radio telescope for this purpose was made in December 1960, authority to proceed was obtained in the spring of 1962 and the resultant *Mark II* telescope (Fig. 1) is now about to begin its research programmes.

The telescope was designed by Husband and Co. of Sheffield and London, who were responsible for the *Mark I*. Like the *Mark I*, the new telescope is an alt-azimuth instrument, but whereas the former is mounted on bogies moving on a 320-ft. diameter circular railway track to give the motion in azimuth, the *Mark II* is mounted on a single large foundation block. This block carries a 42-ft. diameter roller track ring. The revolving structure is supported on this track by 54 steel rollers each of $11\frac{1}{2}$ in. diameter. The mechanical drive for the azimuth motion is via a driving sprocket to a heavy Renolds chain wrapped round the circular support structure of the upper roller track.

The rotating part of the telescope is a prestressed concrete frame structure, and this forms a platform 85 ft. long and 7 ft. wide at a height of 36 ft. 3 in. above the top roller track. This platform carries three bearings for the elevation motion of the bowl. The means for

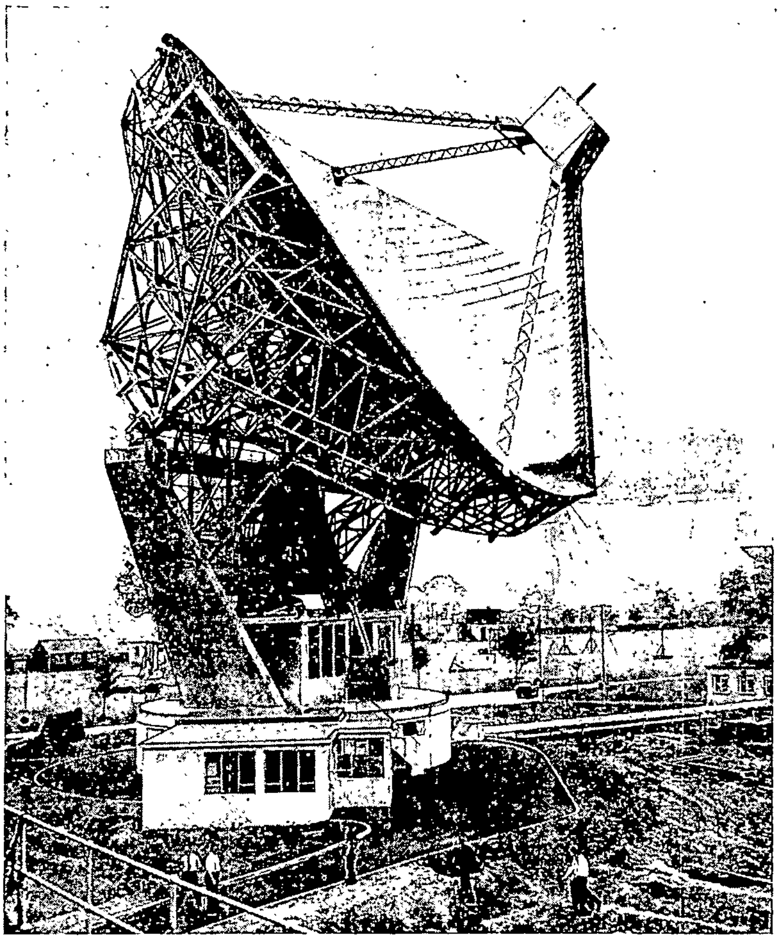

Fig. 1. A general view of the *Mark II* telescope. The 250 ft. *Mark I* instrument is in the background

obtaining motion of the bowl in elevation also differs from that used in the *Mark I*, where two 27 ft. racks were used. In the *Mark II* the motion is obtained by means of a four-start jacking screw 36 ft. 3 in. long by 8½ in. diameter provided with a travelling nut connected to the lower end of a connecting rod which is attached through a pin to the bowl structure at a radius of 40 ft. from its axis of rotation. The elevation motion is from 0° to 95°, which, with a full azimuth motion of 360 deg., gives complete sky coverage.

The driving system in both elevation and azimuth consists of Ward Leonard units with 75-h.p. and 50-h.p. final drive motors respectively, giving an anticipated top speed in still air of 90 deg./min in each motion. The telescope can be operated under full automatic control at wind speeds up to 40 m.p.h. The motion of the telescope will be controlled by a Ferranti *Argus* 104 computer, which will compute and control the azimuth and elevation from a punched tape input to give sidereal or other movement as desired. Once every second the computer converts the sidereal position to azimuth and elevation angles, allowing for precession, and refraction. This occupies 1/4 sec of computer time and is carried out 2 sec in advance of the control. For the control of the telescope, the computer reads and compares the telescope position with the desired position 4 times a second. Voltages representing the speed at which the telescope must move in the next 1/4 sec to correct the differences are then fed out to the servo system. In the analogue system these voltages are compared with voltages representing the actual speeds and the difference is amplified to provide the driving power. Driving accuracies better than 1/3 min of arc are expected.

These functions, together with the production of a complete log of the telescope operations, take only one-half of the computer time. The remaining time is available for other uses, and in some of the research programmes the measurements will be fed into the computer via a data logger for processing in real time.

The reflecting membrane is an elliptical paraboloid with major axis 125 ft. and minor axis 83 ft. 4 in., formed of continuously welded 12 s.w.g. steel sheets. The focal length is 40 ft., and just above the focal point there is an 8-ft. cube laboratory supported on four legs rising from the bowl structure near its edge. The original specification called for a shape tolerance of ± 0·5 in. in the bowl, at all angles of elevation and azimuth positions and, as built, the bowl profile is correct to ± 1/8 in. Within these limits the telescope should work at full efficiency down to wave-lengths of about 1 cm.

The theoretical beam-width and power gain of the *Mark II* as a function of wave-length are shown in Figs. 2 and 3, together with the observed values for the *Mark I* in the overlapping wave-length region of interest. Unexpectedly, the *Mark I* has remained the largest completely steerable telescope in the world. The new instrument has no such claim to be large by world standards, but it will probably be the largest steerable telescope capable of work at wave-lengths of only a few centimetres. (The performance of the Australian 210-ft. Parkes telescope is falling off at wave-lengths below 10 cm and the Russian and American telescopes which remain good down to a few centimetres are smaller than the *Mark II*.) Further, we believe it to be the only large radio telescope under the direct control of a digital computer.

From Fig. 2 it is seen that the anticipated beam-width between half-power points in the azimuth direction is

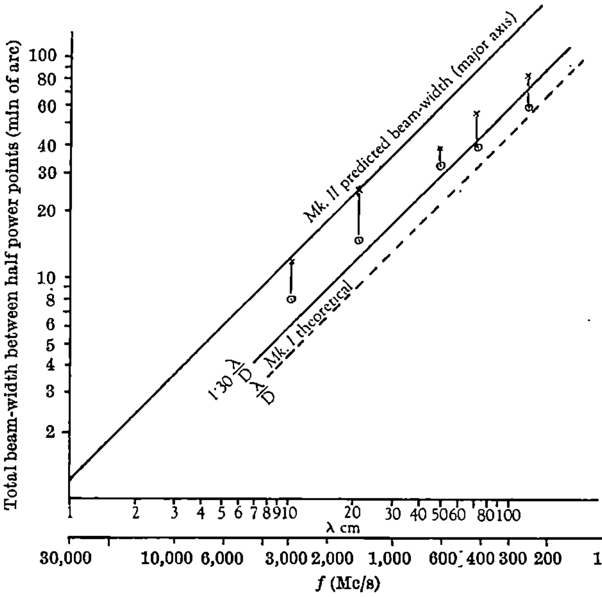

Fig. 2. Theoretical beam-widths of the *Mark I* and *II* telescopes compared with the observed values for the *Mark I*. ×, *E* plane; O, *H* plane

Pergamon Press Publications

Carbon

An International Journal sponsored by the American Carbon Committee
Editor-in-Chief: S.Mrozowski, Department of Physics, University of Buffalo, New York
Supported by a board of Associate Editors and by an Honorary Editorial Advisory Board

This new quarterly journal is devoted to the physics, chemistry, and the scientific aspects of the technology of a class of materials ranging from organic crystals and polymers through chars and carbons to graphite. By providing a medium for the exchange of knowledge and techniques the journal aims to further understanding of this distinct group of solids. It publishes original research papers, occasional reviews of limited problems, and an important reference section (by title) to carbon research published elsewhere.
Subscription rates and a specimen copy will be sent on request.
Contributions are invited for editorial consideration and, if accepted, rapid, world-wide publication. Full details for submission of manuscripts are given in the journal—write for a specimen copy.

Selected Works in Organic Chemistry

A.N.Nesmeyanov, U.S.S.R. Academy of Sciences

Chapter Headings:
Diazomethod of synthesis of organometallic compounds; Synthesis of organometallic compounds; Quasicomplex and unsaturated organometallic compounds–tautomerism and beta-conjugation; Stereo-chemistry of substitution reactions; Ferrocene and metal carbonyls; Organic compounds of Si, Ti, F; Synthesis on the base of beta-chlorovinyl ketones; Synthesis of polychlorhydrocarbons and related compounds and their chemical conversion.
1,200 pages. Approx. £12

The Gas Phase Oxidation of Hydrocarbons

V.Ya.Shtern, Institute of Petrochemical Synthesis, U.S.S.R. Academy of Sciences

Partial Contents:
Hydroxylation scheme; Peroxidation scheme; Aldehyde and dehydrogenation schemes; Di-radical chain schemes of methane oxidation; The mechanism of propane oxidation; The role of carbon monoxide in methane oxidation; A scheme for methane oxidation (1958) and its quantitative calculation.
724 pages. £10 ($28.50)

Organic Geochemistry

Edited by I.A.Breger, U.S. Geological Survey

Partial Contents:
Prebiological formation of biochemical substances – S.W.Fox; Geochemistry of humus – F.W.Swain; Geochemistry of kerogen – J.P.Forsman; Geochemistry of coal – D.W.Van Krevelen; Geochemistry of crude oil – W.L.Whitehead; Geochemistry of miscellaneous naturally occurring carbonaceous substances – G.Mueller; Geochemistry of pigments – H.N.Dunning; Geochemistry of amino acids – P.A.Abelson; Geochemistry of carbohydrates – J.R.Vallentyne.
International Series of Monographs on Earth Sciences, Volume 16
734 pages. £7 ($22.50)

Proceedings of the Fifth Conference on Carbon, in two volumes

Edited by S.Mrozowski, Department of Physics, University of Buffalo, New York, P.L.Walker, Pennsylvania State University, and M.L.Studebaker, Phillips Chemical Company, Ohio

Partial Contents of Volume 1:
Formation of spin centers in carbon by oxidation and their thermal anneal – K.Antonowicz; The catalytic properties of amorphous carbons – D.E.Weiss; Mechanism of radiation damage to graphite at high temperatures – D.R.de Halas and H.H.Yoshikawa; Large graphite columns in the core of the experimental gas-cooled reactor (EGGR) – J.V.Neely; Technique for microscopic studies of graphite – R.L.Hales and E.M.Woodruff; Compaction of artificial graphite – J.R.May
624 pages. £7 ($20.00)

Contents of Volume 2:
Electronic properties; Surface properties, adsorption and reactivity; Irradiation effects, gas permeability; Carbonization, graphitization and structure; Mechanical and thermal properties, imperfections; Author index; Subject index.
686 pages. £7 ($20.00)

The Production of Olefine-Containing and Fuel Gases

Ya.M.Paushkin and T.P.Vishnayakova

Chapter Headings:
Introduction: Methods of chemical treatment of gases and products from the pyrolysis of crude oil; Raw materials for the process of gasification; A theoretical presentation of the high temperature pyrolysis of hydrocarbons; The pyrolysis of hydrocarbon stock and resins; Contemporary installations for the gasification of liquid fuels.
247 pages. 70s. ($10.00)

Carbon Oxidation in the Weld Pool

A.Apold, Fonas Fabrikken a-s, Oslo

Partial Contents:
Details of the determination of the carbon balance; Observations of boil in the pool; Variation of carbon balance with experimental conditions; Total carbon oxidation during the welding process and total carbon oxidation in the pool; Measurement of steel losses during welding; Random errors; Temperature distribution in electrode crater arc and pool; Reactions in electrode crater and arc; Reasons for the variation of carbon balance with changes in current and rate of travel.
143 pages. 35s. ($7.00

NEW MULTI-PURPOSE POTENTIOMETER

- Functionally designed
- Simple to use
- Easy to service (e.g. galvanometer replaceable by user)
- Range 0.01 to 101 mV
- Accuracy ±0.1%
- Discrimination 0.002 mV
- Resistance 200 ohms/volt

Portable and robust, the new Cambridge Multi-purpose Potentiometer replaces the earlier highly successful workshop potentiometer. Primarily designed for testing or calibrating thermocouples and associated indicators or recorders in situ, it is completely self-contained, incorporating a potential source and galvanometer; and can also be used for many forms of laboratory measurement. Two dials cover the whole range, which can be extended with simple accessories.

Cambridge Instrument Company Limited, 13 Grosvenor Place, London, S.W.1

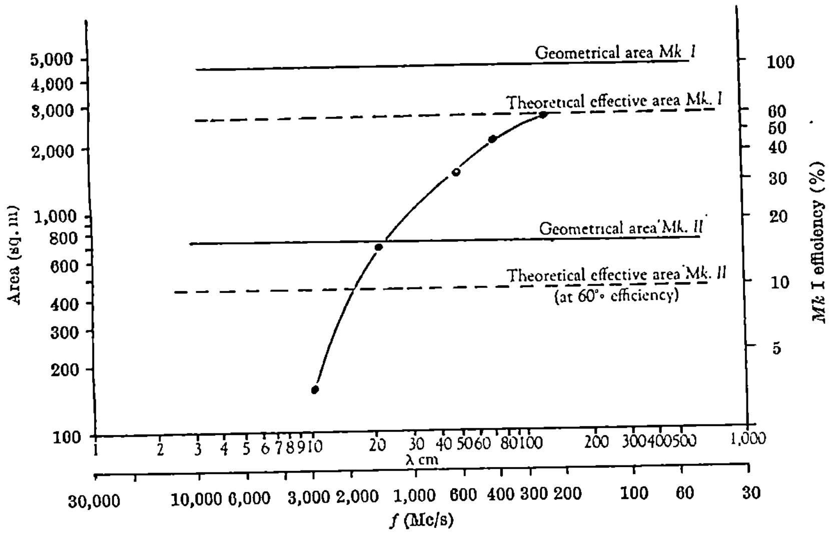

Fig. 3. Effective area and efficiency of the *Mark I* compared with the theoretical effective area of the *Mark II*

6 min of arc at 5 cm, and in the event of the telescope working at full efficiency at 1 cm the beam-width will be only 1·2 min of arc. This presents a considerably greater steering difficulty than in the *Mark I* where at the lowest wave-length on which it is used (21 cm) the beam width is 15 min of arc. The computer itself is capable of driving the telescope with an accuracy of ± 1/3 min of arc and it is necessary to align the elevation and azimuth position pick-offs of the telescope and to determine the collimation errors to this accuracy.

In order to do this initially, and to provide subsequent routine checks, an 8-in. optical telescope aligned along the elevation axis is mounted in a cabin behind the vertex of the bowl. In order that this telescope can be used at all elevations the observer is provided with a pivoted chair in this cabin. Thus the position of a stellar image relative to the axes of the telescope can be determined at any telescope setting. Since the direction of the radio beam depends on the position of the focus box relative to the paraboloid, separate measurements including calibration on known radio sources will be necessary to determine the radio positioning error. The vertex cabin is also equipped with a television camera so that the stellar images can be seen in the control room. Although this arrangement is primarily for the setting up and checking procedures, it is expected to be valuable in future combined optical and radio observations.

When these collimating and alignment tests are completed, the telescope will be used to measure the spectra of several hundred radio sources at wave-lengths of 11 cm and 6 cm. This is a straightforward programming operation which will give experience in the use of the digital computer to drive the telescope, and will extend the spectral measurements of the radio sources already made on the *Mark I* down to 21 cm[3,4]. It is hoped that the variations in spectral shape may give important information about the processes of emission in the distant radio galaxies. Simultaneously performance tests will be made at wave-lengths of 3 cm and lower. Polarization measurements on the planets and the radio sources will follow this programme and later in the year it is hoped to use the *Mark II* and the *Mark I* as an interferometric pair in the 21-cm band, both continuum and *H* line—in the latter case for the examination of the neutral hydrogen structure of extragalactic nebulæ.

The centimetre part of the spectrum has become a region of great interest and importance during the past few years, and the availability of the new telescope in this wave-band coupled with the high performance of the 250-ft. instrument in the metre wave-band provides the United Kingdom with unsurpassed facilities for research in radio astronomy.

A CHEMICALLY SPECIFIED MOLECULAR MECHANISM UNDERLYING EXCITATION IN NERVE: A HYPOTHESIS

By Prof. JULIAN M. TOBIAS
Department of Physiology, University of Chicago

Nerve Excitation

HOW an axon shifts from the resting to the excited state can be discussed in terms of three groups of phenomena. First, there is depolarization. Secondly, there is a complex of sub-molecular, molecular and macromolecular level events which are initiated by the depolarization. Thirdly, if the depolarization is sufficient the second class of events grows to a point where membrane resistance falls and the ion fluxes characteristic of the fully developed excited state[1,2] are permitted to occur. These three sets of changes overlap and interact in time, but can be discussed separately. The word 'excitation' refers to the first and second sets.

Research emphasis for many years has been focused primarily on phases 1 and 3 above, and much is known about their important electrophysiological and electroionic components[1-3], whereas relatively little work has been done on phase 2 which is now so greatly challenging. Nevertheless, enough information is at hand so that it should be fruitful clearly to state a limited but chemically specified working hypothesis about phase 2, to collate the relevant evidence, to verbalize certain questions raised by the hypothesis, and to notice some of the experiments it suggests. Although it is pertinent for other excitable cells and for junctions, and although it is suggestive for recovery phenomena, the hypothesis will, for the sake of simplicity, be presented only in terms of axonal excitation.

Statement of Hypothesis

The early, catelectrotonic, outward, exciting current moves potassium from the axoplasm into the membrane phase. This intruding potassium displaces calcium from polar carboxyl and/or phosphate groups on membrane phosphatidylserine. As one consequence, water content increases in the membrane phase. The combined calcium displacement and increased hydration cause, and are paralleled by, loosening and spreading apart of membrane structural components, phospholipid being the most important. A change in geometry of the membrane protein increases this spatial deformation. The three events: (*a*) catelectrotonic injection of potassium into the membrane phase to displace calcium (ion exchange); (*b*) water moving into the membrane phase (hydrokinesis); (*c*) protein deformation of the membrane (proteokinesis), are responsible for the reversible change in membrane structure which expresses itself as a fall in membrane resistance permitting the ion fluxes of activity to supervene.

Separation of and Evidence for Propositions Explicit or Implicit in the Hypothesis

Proposition 1. Catelectrotonic, outward cation flow, not anelectrotonic inward cation flow, is exciting: (*a*) The evidence that excitation occurs where positive current flows out of the cell cathodally, and not where it flows inward anodally, is too extensively documented to require support here[4,5].

(*b*) The argument that it is an ion displacement current which excites does require clarification, since it is often stated that ". . . in the squid axon the three variables, sodium conductance, potassium conductance and inactivation, are governed solely by membrane potential. . . ."[6]. This can be misinterpreted, and is sometimes considered to mean that ion displacement current has been excluded as a causal factor in the excitation process. In fact, however, when the membrane potential is suddenly reduced (depolarization), an initial pulse of capacity current precedes the large currents carried chiefly by sodium and potassium moving down their own electrochemical gradients, and to account qualitatively for the propagation of an action potential the sequence of events at each point on the nerve fibre is as follows: Current from a neighbouring active region depolarizes the membrane by spreading along the cable structure of the fibre. As a result of this depolarization sodium current is allowed to flow (adapted with minor changes from reference 7). Thus, both in the case of the space clamped membrane action potential and in normal propagation, the ionic currents of the spike proper are preceded by an outward current, a spatial displacement of ions.

The hypothesis deals with the events initiated by this early outward current which lead to the excited state.

Proposition 2. Outward exciting current moves potassium from the axoplasm into the membrane phase. (*a*) Some charged particles must carry the early outward current even if they only move on to and off a high capacity structure of some sort in the membrane phase rather than through the dielectric. The most likely candidate for the role of the particle which normally carries this current into the membrane cathodally is potassium derived from the superficial axoplasm under the membrane.

(*a* 1) Potassium does move toward a cathode in electrically polarized nerve[8,9] and moves there with a mobility close to that in water[9].

(*a* 2) In spite of the relatively high mobility of axoplasmic potassium, mobility alone would favour H^+ (λ_c = 349·8) over K^+ (λ_c = 73·5) ions for carrying the current by a factor close to 5 if the mobilities in water are used for the calculation. However, concentration difference in the axoplasm gives K^+ an advantage over H^+ of about 10^6 times. Therefore, considering only mobility and concentration, potassium will supply an overwhelming number of highly mobile axoplasmic current carriers.

(*a* 3) Potassium efflux at a cathode approximately accounts for the outward current there[10].

(*a* 4) The mean potassium transference number for current flowing out of the squid axon perfused with $(K^{42})_2SO_4$ is about 1·09 (ref. 11).

Proposition 3. There is calcium in the membrane phase: (*a*) There are two pieces of direct evidence.

(*a* 1) Micro-incineration followed by microscopy of myelinated nerve shows the calcium to be in the myelin and not in the axoplasm[12]. To the extent that myelin is a repeating array of cell-membrane material[13], this shows calcium to be present in the cell membrane. Calcium is also found by this technique to be concentrated at the surface of the neurone soma[12].

(*a* 2) Human erythrocyte ghosts contain about 1×10^{-4} m.equiv. of calcium/mg dry material[14]. To the extent that the red cell ghost is cell membrane this also shows calcium to be present there.

(*b*) There is a large amount of indirect evidence. A few examples follow.

(*b* 1) Calcium is needed for repair of membrane rupture in many cells[15] and decline of the injury potential in excised muscle is accelerated by high calcium in the medium[16]. Both effects presumably are due to the role of calcium in reconstituting membrane structure.

(*b* 2) Calcium decreases the width of the dense, double-edged membranes at the axon surface[17] as well as of bimolecular leaflets of phospholipids extracted from neural tissue and dispersed in water[18].

(*b* 3) The numerous effects of calcium on excitability[19], on permeability[15], and on osmotic hæmolysis[20] also indicate that it reacts with membrane components to modify structure.

(*b* 4) Effects of calcium on phospholipid monolayers will be noted in Proposition 5.

Proposition 4. There is phosphatidylserine in the membrane:

(*a*) The erythrocyte ghost contains phosphatidylserine[21–23].

(*b*) Myelin contains phosphatidylserine[24].

Proposition 5. The calcium in the membrane is, in part at least, combined with the phosphate and/or carboxyl groups of membrane phosphatidylserine:

(*a*) There is no direct evidence for the intact cell.

(*b*) There is impressive evidence from studies on monolayers.

(*b* 1) If monolayers of purified phosphatidylserine (PS), phosphatidylcholine (PC), or phosphatidylethanolamine (PE) are made on a Langmuir trough, adding calcium to the aqueous hypophase condenses the PS film, but has no significant effect on the force-area diagram of films made either of lecithin (PC) or of cephalin (PE). This is true over a range of several units on either side of *p*H 7, therefore including physiological *p*H values[25].

(*b* 2) A Geiger–Müller counter suspended over a Langmuir trough containing radioactive calcium in the hypophase solution shows that spreading a monolayer of PS increases calcium-45 in the surface whereas monolayers of PC or PE have no such effect[25].

(*b* 3) A membrane model made of phospholipid impregnated millipore increases its transmembrane resistance on addition of calcium to the ambient medium[26], but only if the phospholipid is PS, not if it is either PC or PE (ref. 27).

These observations are understandable in terms of the acid-base properties of the three phospholipids: PC and PE are nearly electrically neutral around *p*H 7 whereas PS, having three ionogenic groups, a positively charged amino, and two negatively charged acidic groups, phosphate and carboxyl will, at *p*H 7, have at least one negatively charged group available for reaction with cations[28].

Proposition 6. Excitation mobilizes the calcium of the membrane. Potassium, moved into the membrane by the exciting current, is the agent by means of which this mobilization is produced (continued in proposition 7):

(*a*) Excitation increases entry of calcium into and egress from squid axons and muscle[29,30]. Stimulation of the *Elodea* cell permits calcium to move into the vacuole[31].

(*b*) Adding potassium to the outside medium increases movement of calcium into and out of muscle[30].

(*c*) The antagonistic actions of potassium with reference to calcium on electrophysiological properties, permeability, and structure of cells and of various colloidal systems also support the view that potassium can displace calcium.

Proposition 7. The calcium, so displaced by potassium, is displaced from membrane phosphatidylserine polar groups:

(*a*) Here it is possible to say that potassium can displace calcium from myelin and from phosphatidylserine. Direct data on cells are lacking.

(*a* 1) Monovalent cations displace calcium from bovine nerve myelin in the order lithium = sodium < potassium < rubidium < cæsium[32].

(*a* 2) The condensation of a monolayer of PS due to absorption of calcium from the hypophase is prevented by potassium[25].

(*a* 3) Radioactive calcium adsorbed to a PS monolayer is displaced by potassium[25].

(*a* 4) The rise in resistance produced in the phospholipid membrane model by addition of calcium is reversed by potassium chloride[26],[27].

(*a* 5) Direct chemical analysis (flame photometry) shows that calcium taken up by the phospholipid membrane model can be displaced by potassium, and the replacement obeys the rules of ion exchange phenomena[33].

Proposition 8. These events, cathodally produced potassium intrusion and calcium displacement from phosphatidylserine polar groups, are followed by increased water entry into the membrane phase.

(*a*) Many experiments show that water content of whole cells is increased by adding K^+ ions to the medium and is decreased by Ca^{++} (see bibliography in ref. 25). There is also evidence that water content of axons is increased during activity[34,45].

(*b*) In electrically polarized axons the cathodal region swells, increases in transparency, and becomes soft and sticky[35,36], these effects being ascribable to water migrating cathodally.

(*c*) In electrically polarized axons specific gravity of the axoplasm decreases cathodally coincidentally with the swelling. This is also ascribable to water migrating cathodally[37].

(*d*) As mentioned under Proposition 3, X-ray diffraction shows that potassium increases and calcium decreases lamellar spacing of nerve myelin lipid extracts dispersed in water[16], and calcium decreases the spacing of squid axon surface lamellæ[17], both effects presumably being due to hydration changes.

(*e*) A carboxylic acid membrane, made from polyvinylmethylether and polyacrylonitrile plus vinylchloride, shrinks and loses from a half to a third of its water on going from the potassium to the calcium state[38].

(*f*) Recent experiments on the phospholipid membrane model show that potassium increases and calcium decreases water wettability, water content, and water permeability of the model[26,39].

(*g*) The water content of myelin extracted from bovine nerve is increased by potassium and decreased by calcium[32].

(*h*) Myelin in water forms an oil-in-water emulsion in the presence of potassium and a water-in-oil emulsion in the presence of calcium[40].

(*i*) The water content of red cell ghost fragments is increased by potassium and is decreased by calcium[14].

Proposition 9. Membrane protein contributes to the structural deformation of the membrane which is permitted by calcium displacement and started by water intrusion:

(*a*) There is one bit of direct evidence which suggests, though it does not prove, that protein may participate directly in the genesis of the change permitting the ion fluxes of activity. Protease injected into the axoplasm of the squid giant axon destroys excitability without interfering with the resting potential[41]. Such persistence of the resting potential indicates that potassium and sodium segregation and membrane resistance and capacity are maintained. Phospholipases, on the other hand, which also produce inexcitability, *in addition cause the resting potential, resistance and capacity to fall to zero*[37]. These findings suggest that integrity of the phospholipid in the cell membrane is mandatory for the high resistance and capacity which make the ion segregations and resting potential possible, and that protein is somehow involved in a reversible modification of the orientation, packing or structure of the phospholipid to permit the ion fluxes of activity[34,42]. *An interdependence of lipid and protein geometry in the axon membrane is strongly indicated by* electronmicroscopically demonstrable changes in the membrane protein component after phospholipid hydrolysis[42,26b]. This change would, according to the present view, co-operate with calcium displacement and increased hydration in producing the shift of membrane structure from the resting to the active state.

(*b*) Squid axon ATPase activity is concentrated in the sheath region, not in the axoplasm[43]. One wonders if this enzyme may be a contractile protein associated with the membrane and capable of deforming it, since certain nerves have been shown to change surface contour and to shorten reversibly with activity[44–46].

Conclusion

Displacement of membrane calcium by potassium (ion exchange event), increased membrane hydration (hydrokinetic event) and membrane protein deformation (proteokinetic event) underlie the reversible change in membrane structure (primarily phospholipid geometry) which expresses itself as: (1) a fall in resistance with (2) increased transmembrane fluxes of sodium and potassium, both being major signs of the excited state in nerve cells.

Additional Points and Queries

Propositions 2, 6 *and* 7. (*a*) Why does axoplasmic potassium not diffuse into the membrane phase to displace calcium and produce the excited state continuously ? Why must it be driven into the membrane as an outward current ?

To keep potassium out of the membrane phase is probably a function of the resting potential[47]. Assuming that only a few potassium ions need diffuse out of the axoplasm, leaving their non-diffusible anions behind, to produce the resting potential, these few do not displace enough membrane calcium to shift the membrane to the active state, and the resting potential so generated, being close to the potassium equilibrium potential, prevents further movement of axoplasmic potassium into the membrane phase.

This concept is supported by a recent experiment[48]: Normally, both axons and muscle cells become inexcitable if the resting potential is kept low. However, if internal potassium is reduced sufficiently, then axons are excitable even at zero resting potential. In terms of the present hypothesis this would be explained by arguing that when potassium is present internally in normal concentration, then a large resting potential is necessary to keep this potassium out of the membrane (the equilibrium potential is high) so that the high resting impedance of the membrane can be *maintained* until the exciting stimulus is applied. If, however, there is little or no potassium in the axoplasm, then little or no resting potential is needed to keep it out of the membrane phase (the equilibrium potential is low), and in this condition the system can be excited from a low or zero resting potential level.

(*b*) How much potassium is moved into the membrane phase by the early, exciting, outward current ?

An average of about one potassium ion per 45,000 sq. Å of membrane area can be calculated as the amount of potassium which is moved into the membrane catelectrotonically by the time threshold is reached. This is computed from the action current at the frog node of Ranvier[36], from squid axon membrane capacity[10] and from the number of coulombs of outward current per cm^2 needed to excite the squid axon[7]. Since, however, if 1 per cent of the membrane area became freely conducting the resistance as a whole would fall to about 0·002 $\simeq$ cm^2, and since membrane capacity changes little with activity, it can be argued that perhaps as little as 0·001 per cent of the area is involved. Thus, considering the membrane to be 100 Å thick, and if only 0·001 per cent of the area were involved, the concentration change due to the current carrying K into this volume of membrane would be about 37 millimolar by the time threshold is reached. It has been found that something between 10 and 100 millimolar potassium reverses the effect of 1 mM calcium on the phospholipid membrane model and displaces calcium from the phosphatidylserine monolayer[25]. For an internal concentration of potassium of 0·1 M the number of potassium ions needed for the foregoing change could be supplied from a sub-membrane layer about 5 Å thick.

(*c*) If depolarization moves potassium into the membrane phase and this leads to structural dispersion with a fall in resistance, what keeps membrane resistance relatively high during the prolonged plateau of depolarization normally shown by heart muscle[49], and by nerve treated with tetraethylammonium or certain metal ions[50] ?

Here it is suggested that after potassium displaces calcium from phospholipid during excitation in the presence of TEA or nickel, then, during recovery, these unusual ions in turn displace potassium and occupy the sites which would normally be reoccupied by calcium. If they bind to phospholipid more tightly than calcium does, then they would tend to stabilize the membrane structure in the high resistance state, and prevent potassium egress, thus delaying repolarization. As time passes, however, the persisting low potential will eventually permit enough potassium to accumulate in the membrane to displace the binder ion. When this finally occurs the potassium will flow out and repolarize the cell. In this way the persistence of relatively high resistance even in the presence of depolarization could be accounted for. Experiments on the quantity of outflowing current required to excite under these circumstances and on tenacity of TEA and nickel binding to phospholipid as compared to that for calcium could be done fairly easily and would clarify this problem. What substance normally present in heart muscle might produce this effect is not apparent, but the suggestion that such a substance exists may stimulate interesting experiments.

(*d*) Since neither the phospholipid membrane model nor the monolayers used so far show any ability to distinguish potassium from sodium, what protects the phospholipid–calcium complex from external sodium ?

No satisfactory answer is at hand. It has already been suggested here that it is probably the resting potential which protects the resting membrane from potassium, but we do not know what protects it from sodium. Failure to answer this question, however, does not weaken the hypothesis. It does emphasize the fact that one still does not know how cells distinguish sodium from potassium.

(*e*) Perfusion of the squid axon with low-potassium or potassium-free solution does not prevent excitation[48]. How can this be reconciled with the argument of the hypothesis that it is catelectrotonic injection of axoplasmic potassium into the membrane which displaces calcium to start the structural changes which permit the fall in resistance to ion fluxes ?

First of all, as internal potassium is decreased, an increasing amount of depolarization is needed for the membrane resistance to fall to a given value[16]. Since a change in membrane resistance is probably our best evidence of a change in structural state, this finding supports the hypothesis. Thus, in terms of the hypothesis, the less potassium there is inside the axon the more depolarization should be required to permit enough potassium to enter the membrane phase to shift it to the low-resistance state.

Secondly, it is not argued that K^+ is the only cation which can be moved into the membrane phase from inside to displace calcium from negatively charged sites there. We know that sodium is about as effective as potassium in displacing calcium from phosphatidylserine[25]. What is argued is that when potassium is the dominant internal cation, then it is the ion which is moved into the membrane to produce this effect. It is, so to speak, the ion which the cell normally uses to trigger excitation. In the experiments quoted[48] there always had to be high external sodium. This sodium would be expected to leak continuously into the inside perfusate and under these circumstances almost surely would the cation be moved outward by the outwardly directed exciting current to displace calcium from the membrane structure. Thus, the potassium-free perfusion experiments do not pose a serious problem for the hypothesis.

Proposition 3. It becomes ever clearer than an explicit demonstration is required of what calcium is associated within the cell membrane. The evidence for certain reasonable assumptions has been given, and the possibility of combination with nucleic acids has also been investigated[51], but there are no objective experimental data yet available which apportion membrane calcium among the several likely membrane components.

Proposition 8. Since cells are highly permeable to water, that is, if there is a relatively high partition co-efficient for water in the membrane, why should increased membrane hydration increase permeability for ions ?

The fact is that the resting cell membrane may not be significantly hydrated in spite of high water permeability. Thus, the normal red cell surface is relatively hydrophobic[52], the denuded *Arbacia* egg in calcium chloride coalesces more readily with oil than when it is in potassium chloride[53], myelin and red cell ghosts contain less water in the presence of calcium than in potassium[32,14], myelin forms a water-in-oil emulsion in the presence of calcium and an oil-in-water emulsion in the presence of potassium[40], and for many resting cells a high oil : water partition coefficient favours penetration. Therefore it would appear that water can penetrate what may be a water-poor cell membrane phase just as it can to a degree penetrate the hydrophobic part of evaporation retarding monolayers used to conserve water in reservoirs and lakes[54]. Presumably, however, ions could not penetrate significantly by the same pathway and would require increased hydration with formation of water-filled conduits.

Clearly experiments need to be done to determine if axon membranes do in fact become more hydrophilic when excited. Some starts have been made which suggest that water entry into axons increases during activity[34,35,37,45].

Proposition 9. The nature and role of protein in membrane excitation are almost completely unexplored[55,56]. Recent work on a membrane model made of a bimolecular lipid leaflet in water[57] suggests that excitability is conferred on the system only after addition of a specific protein. Even though ATPase was long ago shown to be concentrated in the axonal sheath structure[43], there are not yet any reports of serious attempts to find a contractile protein in nerve cell somata or fibres.

Magnitude of the Transmembrane Potential

It has been argued[36] that the fraction of the resting potential which still exists after threshold is reached at about 15 mV depolarization could do a significant amount of work on membrane components which had been released from mechanical restraint by unbinding of calcium and intrusion of water and which were exposed to this voltage gradient. Thus, it was calculated that a voltage of 50 mV across 100 Å (50,000 V/cm) could move a molecule the size of serum albumin through a distance of 100 Å in about 3×10^{-4} msec. This figure represents maximum speed assuming application of the full voltage and mobility as in water. The velocity is so great, however, compared with the local duration of the nerve impulse, that even with considerable attenuation, say,

1×10^3 or so, such a phenomenon might still play a significant part in altering surface ultrastructure. In addition, it might not be necessary to produce appreciable translation of the liberated membrane component; only a change in orientation as in alignment or disalignment of a dipole might be required. If such a device were operative, then one would add electrokinesis to ion exchange, hydrokinesis and proteokinosis as basic components of the excitation process. The recent finding that a persistent zero resting potential can be tolerated without immediate disastrous consequences[46] de-emphasizes this concept somewhat. Nevertheless, such steep voltage gradients may have important consequences in other contexts.

HORMONES, AMINO-ACID TRANSPORT AND PROTEIN SYNTHESIS

By Dr. STANTON SEGAL

National Institute of Arthritis and Metabolic Disease, National Institutes of Health, Bethesda 14, Maryland

CONSIDERATIONS of the availability of metabolic precursors for utilization by intact cells have evoked considerable interest in the process by which small molecules such as sugars and amino-acids penetrate into the intracellular confines of the plasma membrane. With regard to amino-acids, several mammalian systems such as Ehrlich ascites cells[1], human leucocytes[2], intestinal mucosa[3] and kidney cortex slices[4] have been examined to ascertain the characteristics of such a transport system. The process appears to be dependent on aerobic metabolism, has ionic requirements for sodium and potassium, and behaves in a fashion consistent with carrier mediation, that is, the data fit the concept of the presence of a saturatable binding site(s)[5]. The functional result of this process is the concentration of amino-acid within the cell to levels several times greater than that in the fluid in which the cell is immersed.

It is not surprising that attention should be focused on regulatory aspects of concentrative transfer by hormones in animal tissue since increased secretion of hormones or their administration is associated with growth or hypertrophy of tissues known to be target organs. A propelling factor stimulating the interest in hormone-amino-acid transport relationships has been the known effects of insulin[6–8], growth hormone[9], and œstrogen[10], which increase amino-acid incorporation into proteins of certain tissues. Although these hormones may affect the protein-synthesizing mechanism directly, an important question has been raised concerning the dependence of protein synthesis on transmembranous movement of amino-acids and the size of the intracellular amino-acid pool.

Perusal of the published literature on the subject of endocrine control of amino-acid transfer reveals experiments of varied design which report an alteration by a hormone of the intracellular concentration of an amino-acid with regard to the extracellular medium. The purpose of this article is to review these data and evaluate them within the present concepts of amino-acid transport. In addition, an attempt will be made to put the relationship between transport of amino-acids, the size of intracellular pools and protein synthesis into perspective.

Hormonal Effects on Amino-acid Accumulation in Intracellular Fluid

Three basic types of experimental procedures have been employed to obtain the results summarized in Table 1. These are:

(1) *In vivo* administration of a hormone at a suitable time after *in vivo* administration of a radioactive amino-acid followed by analysis of the amino-acid in the tissue water or cellular fluid of various organs. Experiments of this type have been performed for growth hormone, cortisone, and œstrogen[11] and ACTH[12]. A variation of this type has been used where the hormone (cortisone[13]) has been given to the intact animal, and the change in concentration of all natural amino-acids measured in cellular fluid.

Table 1. Hormonal Effects on Amino-acid Accumulation

Hormone	Amino-acid	Type of study		Tissue	Accumulation of amino-acid	Incorporation into protein†
		Hormone	Amino-acid			
Growth	AIB*	*Vivo*	*Vivo*	Muscle, liver, intestine, kidney	Increased (ref. 11)	Increased (ref. 9)
	L-histidine, L-alanine, AIB	*Vitro*	*Vitro*	Muscle	Increased (refs. 18, 41)	
Adrenocorticotrophic (ACTH)	AIB	*Vivo*	*Vivo*	Adrenal	Increased (ref. 12)	Unchanged (ref. 44)
Cortisone	AIB, others	*Vivo*	*Vivo*	Liver, muscle	Increased (refs. 11, 13)	Increased (ref. 42)
	L-histidine	*Vivo*	*Vitro*	Muscle	Decreased (ref. 15)	Decreased (ref. 15)
Thyrotropic (TSH)	AIB	*Vitro*	*Vitro*	Thyroid	Increased (ref. 27)	Increased (ref. 43)
Œstradiol	AIB	*Vivo*	*Vivo*	Uterus	Increased (ref. 11)	Increased (ref. 10)
	AIB	*Vivo*	*Vitro*	Uterus	Increased (ref. 14)	
Insulin	Several	*Vitro*	*Vitro*	Muscle	Increased (refs. 16, 17)	Increased (refs. 6–8)

* α-Aminoisobutyric acid. † Of utilizable amino-acids.

(2) *In vivo* hormonal treatment followed by measurement of amino-acid uptake by excised tissue *in vitro* such as performed for œstrogen[14] and cortisone[15].

(3) The addition of both hormone and the amino-acid to be examined to tissues *in vitro*. Experiments of this type have been performed with insulin[16,17], growth hormone[18], œstrogen[14], follicle-stimulating and interstitial-cell-stimulating hormone[19]. In several instances conflicting results of hormone stimulation of amino-acid accumulation have occurred between experiment of the first or second types and the third, where hormone was supplied with amino-acid *in vitro*. Discrepancies have thus been reported for cortisone with muscle[13], growth hormone with rat kidney or intestine[20], and œstrogen with uterus[14].

Some critical questions must be asked of nearly all these reported experiments. Primarily, have the observed findings actually resulted from an increase in the unidirectional movement or flux of the amino-acid into the intracellular fluid? Have the hormones which cause increased accumulation of amino-acid within the cell actually altered the membrane mechanism for movements of these molecules?

To facilitate answering the first question, a conceptual image of the cell bathed by nutrient medium can be proposed. Amino-acids, by an energy-dependent process, traverse the cell membrane and enter the cellular fluid. Once within the cell, multiple fates may be possible for the molecule. It may be catabolized, incorporated into protein, or egress from the cell back into the surrounding medium. As the active transport process of influx continues, intracellular levels of free amino-acids are built up until the entry is balanced by the combined rates of the processes regulating the fate of the intracellular molecules. Thus, a so-called steady-state concentration of the amino-acid is achieved the value of which is in excess of that in the extracellular fluid. This simplified concept of the extracellular–intracellular amino-acid may be regarded as a two-compartment system[21]. The amino-acids within the cell are believed to be free and unbound to any specific sites[22].

With the foregoing model in mind it becomes obvious that any single observation of an intracellular amino-acid concentration in the steady-state, as has been reported in experiments of the first type, does not present an adequate explanation of how the steady-state level was altered, in most cases increased. It is not known from data of this type whether the actual influx of amino-acid is increased or whether the effect is to decrease the subsequent loss of the amino-acid from the intracellular pool. Since the non-metabolizable amino-acid α-aminoisobutyric acid (AIB)[23] has been used in many experiments, only the efflux of the amino-acid to the extracellular fluid need be considered with regard to the possible fate of the intracellular molecules. A satisfactory explanation for the reported hormone-produced increase in amino-acid levels within the cell could be a blockade of efflux, as well as a stimulation of the inward transport rate, or both. In the experiments of type 2 or 3, where intracellular accumulation with respect to time has been observed (growth hormone[18] and insulin[16]), a clearer picture of the events leading to a new steady state is obtained. Although the data reported for growth hormone and insulin are suggestive of stimulation of influx, definitive analysis remains to be performed. Compartmental analysis of a kidney slice system[24] has shown that experimental alteration of influx rates almost invariably produces changes in efflux rates so that increase or loss of amino-acids from the intracellular pool may be a composite of flux alterations. Kinetic data have recently been presented showing that the remarkable increase in amino-acid accumulation caused by phlorizin in kidney cortex slices is due primarily to a diminution of efflux[25]. The evidence also suggested that phlorizin may be associated with intracellular binding of amino-acids.

With regard to the membrane mechanism for transport of amino-acids, two main features are the coupling of transport to energy metabolism and the apparent role of a saturable binding site(s) in the process. The directional movements and fate of amino-acids are dependent on the energy supplied by the cell. Metabolic inhibitors[26] markedly affect influx and efflux rates and the size of intracellular pools. It is therefore possible that hormonal effects on accumulation may result from changes in metabolism of energy-yielding substrates. For example, the small increase in AIB accumulation caused by thyrotrophic hormone in thyroid gland slices[27] may be a result of the known alterations in glucose metabolism caused by the hormone[28]. Likewise, the increase in AIB uptake in adrenal by ACTH[12] may be a consequence of increased glycogenolysis induced by ACTH[29]. Analysis of hormone effects on the relationship between energy and transport had not been performed to a significant extent.

Most mammalian transport systems of amino-acids conform to the Michaelis–Menten formulation for a saturatable binding site[5]. Experimental determination is possible of an apparent Km giving some indication of alteration of the affinity of the binding site(s) for the amino-acid. Only insulin has been examined in this fashion[17], and although the data are not conclusive they suggest that there is an increased affinity of the binding site caused by insulin. The known binding of insulin to cell membrane is in accord with this. Similar investigations with other hormones on amino-acid transport remain to be performed.

The presently available data, though demonstrating enhanced accumulation of amino-acids induced by hormones in certain tissues, has not clearly delineated the hormonal effects on the parameters of amino-acid transport which control accumulation. Care must be taken in the interpretation of many of the reports cited. These will, no doubt, provide a stimulus for fruitful research.

Relationship of Enhanced Intracellular Amino-acid Levels to Protein Synthesis

Parallel increases in intracellular amino-acid concentration and incorporation of amino-acids into protein are known to be produced by growth hormone[8] and insulin[6–8] in muscle and of œstrogen in the uterus[10]. Does the increased cellular level of free amino-acid arising from hormonal treatment result in increased protein synthesis? The present concept of regulation of protein synthesis places control of the process in the production of messenger RNA or perhaps at the ribosomal level[30]. Recent data suggest that growth hormone affects the aggregation of the protein-synthesizing ribosomes[31] while œstrogen is believed to stimulate formation of messenger RNA[32]. Insulin, on the other hand, increases amino-acid incorporation into protein under conditions where messenger RNA synthesis is inhibited[33]. Besides the control mechanism associated with messenger RNA and the ribosome, does the concentration of the amino-acid itself play a regulatory function in the cell? Can increased protein synthesis be stimulated merely by the increased availability of the intracellular substrate? Do the hormones augment their action at other regulatory sites by providing increased amounts of amino-acid?

Eagle, Piez and Levy[34] assessed the growth rates of human cells in tissue culture as a function of concentration of intracellular amino-acid. They found there was a critical threshold of 0·01–0·05 mM of the amino-acids studied necessary to initiate growth and that the rate of growth reached a nearly maximum value at concentrations only 2–4 times greater than the minimal critical level. Using Ehrlich ascites cells, Riggs and Walker[35] recently found that increasing the intracellular amino-acid level increased incorporation into protein, the rate of increase varying with different amino-acids. A great difficulty in using these results as a model for hormone-induced enhanced intracellular amino-acid levels is the fact that in the foregoing experiments the increase in intracellular concentration was produced by increasing the extracellular levels, whereas with hormone treatment the increase in intracellular level occurs without a similar increase in extracellular concentration.

A very pertinent finding relating intracellular amino-acid pools to protein synthesis is the observation in bacteria[36], rat muscle[37] and rat kidney cortex slices[24] that the kinetics of incorporation of amino-acid into protein are independent of the rate at which an amino-acid enters the intracellular pool. The build-up of an intracellular amino-acid pool is a logarithmic function, while incorporation into protein is a linear one. Theoretically, if protein synthesis is dependent on entry of amino-acid into the extracellular pool, the incorporation into protein should not exhibit linear kinetics until the amino-acid has achieved a steady-state condition, but this is not the case. These types of data have caused speculation that there is compartmentalization of the intracellular amino-acid pools.

In bacteria it is believed that the so-called 'expandable' amino-acid pool is not related to protein synthesis[38]. It has also been observed in a bacterial system that, while cells have stopped growing because of lack of an amino-acid in the medium, the extractable intracellular free amino-acid pool of this deficient amino-acid is at a normal level[39]. In mammalian cells there may be a very small, rapidly turning-over pool which is separate from the general pool and which is directly related to protein synthesis. Kinetically, the incorporation into protein behaves as if the amino-acid was taken directly from the surrounding fluid. Thus the activation of amino-acids for protein synthesis possibly occurs adjacent to the cell membrane[40] and those amino-acids synthesized into protein do not mix with the free intracellular pool. If the latter be true, then experiments correlating amino-acid incorporation with size of the intracellular pool, where the intracellular pool size is increased secondary to higher extracellular levels, may be making an inaccurate correlation.

From the foregoing discussion the following points may be stressed: (1) The terms intracellular accumulation of amino-acid or uptake should not be confused with the term transport of amino-acid, as the former terms represent the summation of movement of amino-acids into and out of cells. (2) Though several hormones have been shown to augment intracellular accumulation of amino-acids, the exact effects on the parameters of transport have not been clearly delineated. (3) Interrelationships of intracellular amino-acid concentration and protein synthesis remain to be clarified. Regulation of protein synthesis by hormonally increased availability of amino-acids remains open for speculation. Judicious attention to the proper design and analysis of experiments should contribute to the understanding of hormone action in this vital area of cell function.

OBITUARIES

Prof. A. Wormall, F.R.S.

ARTHUR WORMALL died in St. Bartholomew's Hospital on May 9 at the age of sixty-four. He will be greatly missed. The high esteem in which he was universally held is aptly epitomized by a remark made some years ago to one of his junior colleagues: "The one thing we envy you most in your department is your professor".

Wormall received his early education at Leeds, graduating in 1921 and joining the staff of the University in 1922. His work as a lecturer and senior lecturer in biochemistry until 1936 can truly be said to have laid the foundations of the Department of Biochemistry which exists in Leeds to-day.

He early developed an interest in problems of immunology; he helped materially to establish the complex nature of hæmolytic complement, and also described the hitherto unrecorded 'fourth component'. His work on proteins modified by nitration, halogenation and treatment with phenyl isocyanate or mustard gas and its derivatives, particularly his original use of correspondingly modified amino-acids as inhibitors of the precipitin reaction between these protein antigens and their specific antisera, work which he commenced as a Rockefeller Medical Fellow working with Landsteiner at the Rockefeller Institute during 1928–29, did much to clarify our present knowledge of the nature of the groupings which determine the immunological specificity of chemically modified proteins.

In 1930–31 he spent a year in Uganda on behalf of the Colonial Office, investigating chemical and immunological problems connected with trypanosomiasis, and developed methods of measuring the persistence of the drug 'Bayer 205' ('Antrypol', 'Germanin') in the blood stream. Although he later carried out work in widely different fields, these two early interests in immunochemistry and trypanosomiasis remained with him all his life.

In 1936 he was appointed to the newly created chair of biochemistry and chemistry in St. Bartholomew's Hospital Medical College (University of London). His great organizing ability, his continual insistence that preclinical biochemistry teaching must be relevant to medicine, and his deep personal interest in all his students and staff, were responsible for the creation of a flourishing department—and a well-beloved chief.

Shortly after he went to 'Bart's', he recommenced work on mustard gas, and during the War led a research group working in Cambridge on the physiological action of mustard gas. It was at this time also that he commenced his work with artificial radioactive isotopes, and he was the first in Britain to use them in biological investigations. It is a tribute to his farsightedness that when he first envisaged the use of the radioactive sulphur isotope, sulphur-35, in his work on mustard gas, its preparation had been described; but it was stated that its β-particle emission was too soft for it to be of any use in quantitative investigations. At this time, too, the worker with artificial radioactive isotopes not only had to manufacture his own measuring equipment, but his isotopes also! Later, when isotopes became more readily available, he extended his use of them to immunological investigations and to investigations on the metabolism of zinc in normal and neoplastic tissues. In 1953 he organized and conducted the First Latin-American Course in Radioisotope Methodology, and was awarded an honorary doctorate of the University of São Paulo.

He was a governor of the Medical College and of the Hospital, and his wise counsel was greatly valued on the many College and University committees on which he served.

He was always eager to create opportunities for integrating more closely the work of the Hospital and the preclinical departments, and it was mainly due to his endeavours that a research project on the biochemistry of skin was initiated in his Department jointly with the Department of Dermatology in the Hospital.

Wormall had a wide circle of friends, and his gentle courtesy and consideration for others endeared him to all. His great charm of manner readily made the most nervous youngster at ease with him, and no trouble was too great for him to take on behalf of anyone who came to him for help or advice.

Until physical disabilities prevented him, he was a keen golfer, and as a true Yorkshireman had an abiding interest in cricket. His election to the M.C.C. in 1956 probably gave him at least as much pleasure as his election to the Royal Society, which occurred in the same year, and his friends will long remember his account of a day at Lord's with a visiting American scientist when his attempts to explain the rules of the game were frustrated for some time by his visitor's unrealized misconception that the two batsmen were on opposite sides.

In 1925 Arthur Wormall was married to Eva Jackson, who survives him. All his friends would wish to tender to his widow, and his two daughters, their heartfelt sympathy in their loss.

G. E. C. FRANCIS

Mr. H. D. Griffith

THROUGH the sudden death of Mr. Harry D. Griffith on April 11, the University of Aberdeen, and the Natural Philosophy Department in particular, lost a member who had given most loyal service for the long period of forty years. Born in 1898 at Clifton, Bristol, he received his early education at Bristol Grammar School and was awarded an open scholarship in 1916. On account of war conditions then in force, this scholarship was not taken up, but on the cessation of hostilities he entered as a scholar of Trinity College, Cambridge, in 1919 and in due course graduated B.A. Thereafter he continued to work in the Cavendish Laboratory under Sir J. J. Thomson and Sir Ernest Rutherford until 1923. In October of that year he came to Aberdeen on the recommendation of Prof. G. P. Thomson (later Sir George Thomson) with the specific idea of assisting in the teaching of physics to medical students. From this early beginning he was soon engaged in the development not only of the teaching of physics but also in the installation of a radon supply to hospitals in various parts of the country. In order to accommodate the required apparatus, an addition to the Department was built, and there Mr. Griffith installed towards the end of the 1920 decade the apparatus which enabled a supply of radon to be available for hospital work for a period of more than twenty years.

In 1932 he was awarded a Rockefeller Fellowship which enabled him to travel abroad. His first visit was to Berlin. There he studied for some months under Prof. Friedrich at the Institut für Strahlenforschung. Owing, however, to the political upheaval in Germany at that time he found it necessary to leave. From Berlin he went to Stockholm and worked under Prof. Sievert at the Radiumhemmet.

The insight he obtained abroad he put to good use on his return. Soon his services were required by various Departments in the Medical School, and, after the erection of the New Infirmary Buildings at Foresterhill, it was found necessary to provide a small laboratory in the Infirmary for his special use. At the same time the personnel required to meet the calls on the medical physics sections gradually increased, the use and direction of which fell very largely on Mr. Griffith.

After the end of the Second World War it became evident that the laboratory accommodation at Foresterhill was insufficient to meet all requirements. As a result it was decided to erect a laboratory fully equipped with research rooms, workshop and office apartments in close contact with the Medical School at Foresterhill. Much of the work in connexion with this project fell to be carried through by Mr. Griffith.

The development of this laboratory, a considerable undertaking in itself, he carried on along with an ample share in the teaching of both theoretical and practical work in the parent Department of Natural Philosophy. In spite of all, he found time to produce several publications and in consequence was elected a Fellow of the Royal Society of Edinburgh in 1954.

From his entry to the University in 1923 until his death in 1964 he devoted his energies wholeheartedly to the development of his subject. Coming as assistant lecturer, he steadily improved his status to that of reader in medical physics in charge of that division in the University Physics Department. His students held him in the highest regard, and referred affectionately to him always as "Harry". Even those who did not come immediately under his care testify to the same warmth of feeling, and all felt that in his death they had lost one who had been their friend.

Further evidence of this ability to inspire lasting affection is exemplified by the friendship between him and two men of different nationalities—one a German. Dr. Zimmer, whom he met when he first went to Germany and with whom he continued to work for the rest of his life; the other an Englishman, H. Heckstall-Smith, who has recounted in his book, *The Doubtful School-Master*, his first encounter with H. D. Griffith in the Cavendish Laboratory, an encounter which led to a life-long reciprocal exchange of ideas and outlooks. When he came to Aberdeen, he met, in the Natural Philosophy Department, Miss J. M. Jack, herself an honours graduate in physics. A friendship grew up rapidly between them, and in 1927 they were married. They have one daughter who graduated with honours in physics. A. E. M. GEDDES

NEWS and VIEWS

Max Planck Medallists of the German Physical Society: Prof. G. E. Uhlenbeck and Prof. S. A. Goudsmit

PROF. GEORGE E. UHLENBECK and Prof. Samuel A. Goudsmit have been awarded the Max Planck Medal of the German Physical Society. This gold medal, one of the highest awards in international science, was conferred on the 106th anniversary of the birth of Planck, the great pioneer of modern physics. Profs. Uhlenbeck and Goudsmit, in 1925, discovered the 'spin of the electron', a cornerstone of present atomic theory. Dr. Goudsmit is also deputy chairman of the Department of Physics in the Brookhaven National Laboratory and managing editor of the American Physical Society. Both scientists received their education in The Netherlands, and joined the faculty of the University of Michigan in 1927. Prof. Uhlenbeck went to the Rockefeller Institute in 1961. Dr. Goudsmit joined the Brookhaven National Laboratory in 1948 and has been a visiting professor in the Rockefeller Institute since 1957. During the Second World War both were connected with radar research in the Massachusetts Institute of Technology. Dr. Goudsmit, moreover, was the scientific head of a secret intelligence mission which moved in with Allied troops and reported, in the winter of 1944, that German scientists had failed to make any significant progress in their work on atomic explosives.

Chemistry in the University of East Anglia: Prof. S. F. Mason

DR. S. F. MASON has been appointed professor of chemistry in the new University of East Anglia at Norwich. Dr. Mason, who is forty years of age, was educated at the Wyggeston Grammar School, Leicester, and Wadham College, Oxford; he graduated with first-class honours in chemistry in 1945, and obtained his M.A. and D.Phil. in 1947. During 1947–53 Dr. Mason was tutor in chemistry at Wadham College and departmental demonstrator in the Museum for the History of Sciences at Oxford; during this period he published a number of papers on the history of sciences and a successful book, *A History of the Sciences*, which has been translated into French, German and Japanese. In 1953 he was appointed Research Fellow in the Department of Medical Chemistry of the Australian National University, then housed in London, where he worked on the ultra-violet and infra-red spectroscopy of heterocyclic compounds. In 1956 he was appointed lecturer in chemistry in the University of Exeter, where he became a senior lecturer in 1961 and reader in chemical spectroscopy in 1963. During his time in Exeter, Dr. Mason published many papers in the fields of spectroscopy, and its application to structural problems, and in theoretical chemistry; during the past two years he has taken up the investigation of optical rotatory power, particularly circular dichroism and optical rotatory dispersion, in which field, too, he has published a number of important papers. Dr. Mason will take up his new appointment on October 1.

Water Resources of England and Wales

A WATER Resources Board is being set up under the Water Resources Act, 1963, and will have the task of advising the Minister of Housing and Local Government on water policy in England and Wales. Its main practical tasks will be to build up comprehensive information about water resources and demands, to work out action needed to augment resources, to secure the promotion of schemes which it recommends and to commission and supervise research. The Board's permanent offices will be outside London, probably in Reading, although at the outset it will operate from Government offices in London. Twenty-nine new river authorities, also set up under the 1963 Act, will supersede existing river boards and will have important new functions relating to the management of water resources, including a licensing control of abstractions and impoundings of water. Statutory consultations about the size and composition of these authorities, which will have a membership of between 21 and 31, and will be the executive arm of the new system, are now going on.

The following have been appointed members of the newly formed Water Resources Board: *Chairman*, Sir William Goode, until recently Governor and Commander-in-Chief, North Borneo; *Deputy Chairman*, Mr. A. G. McLellan, general manager, Sunderland and South Shields Water Co.; *Members*, Mr. R. A. Banks, until recently a director of Imperial Chemical Industries, Ltd.; Prof. H. C. Darby, professor of geography, University College, London, and until recently a member of the National Parks Commission; Dr. Idris Jones, a former member of the Welsh Advisory Water Committee and lately director-general of research, National Coal Board; Mr. W. A. Muddell, chairman of the Executive Council of the River Boards' Association; Mr. N. A. F. Rowntree, consulting engineer (full-time director of the Board's activities).

R337

The Bristol College of Science and Technology

In reply to a question in the House of Commons on June 4, Mr. Quintin Hogg, the Secretary of State for Education and Science, said that the Bristol College of Science and Technology, which is one of the ten colleges of advanced technology destined for university status following the Government's acceptance of the recommendations of the Robbins Report, would have to move from its present site and buildings which it shares with the Bristol Technical College. Mr. Hogg said that following a report from the Governors of the Bristol College of Science and Technology it had been decided that it should be moved to Bath, where a site has been made available for future development. Originally the plan had been to provide new buildings for the College in Bristol, but the earmarked site proved too small for the needs of an expanding university institution. Three alternatives were considered: namely, Clevedon, South Gloucestershire just outside Bristol, and Bath. It was felt that the site at Clevedon was unsuitable because of the difficult contours of much of the area, and that in South Gloucestershire did not offer the opportunities afforded by the Bath site of a close association between university and city.

Return of Britain's Scientists

In a written answer in the House of Commons on June 18, the Secretary of State for Education and Science, Mr. Hogg, stated that most of the scientists and engineers who had so far returned from the United States and Canada in 1964 were seen by the Selection Board in 1963, when 146 candidates were recommended. Thirty-seven of those interviewed were known to have returned so far. In 1964, the Board had recommended about 190, but it was too early to say how many offers of employment would be accepted. The Board paid to candidates in North America their travelling expenses to and from the nearest place of interview and, in suitable cases, employing departments and authorities would pay return fares to the United Kingdom of the successfully assigned candidates and their families.

Advisory Committee on Pesticides and Other Toxic Chemicals

In a written answer on June 18, Mr. Hogg stated that following the assurance given on March 24 by the Minister of Agriculture, Fisheries and Food, the Advisory Committee on Pesticides and Toxic Chemicals had been given a new title reflecting its wide responsibilities. It would now be known as the Advisory Committee on Pesticides and Other Toxic Chemicals, and its terms of reference had been extended to keep under review all risks that might arise from the use of pesticides; potentially toxic chemicals on sale to farmers for veterinary use and veterinary medicines prescribed for use by veterinary surgeons; and any other potentially toxic chemicals specifically referred to the Committee by Ministers; and to make recommendations to the Ministers concerned. The industrial and domestic uses of organochloric pesticides were now being reviewed.

Schools and Society

In a written reply in the House of Commons on June 16, Mr. Hogg stated that following the recommendations of the Newsom Committee for an Inter-Departmental Working Party to consider the general social problems, including education, in slum areas, an Inter-Departmental Committee had been established, with terms of reference covering these problems within a wider context. Its task would be to consider plans for, and results of, research and development work on any aspect of the general theme "The Schools and Society", with the view of the better co-ordination of activities and the more efficient use of public funds and other moneys. The Home, Health and Education Departments for England and Wales and Scotland, the Ministry of Housing and Local Government, the Ministry of Labour and the Department of Scientific and Industrial Research were represented.

National Examinations Board in Foremanship and Supervision

In a written answer on June 17, Mr. Hogg stated that after consultation between his Department and representatives of industry and the professional bodies chiefly concerned, including the British Institute of Management, a new National Examinations Board in Foremanship and Supervision had been set up, with as its first task consideration of the early introduction of a qualification to replace the present British Institute of Management Certificate. The Board might introduce other qualifications in foremanship and supervision if it saw the need, and he hoped to see substantially increased numbers taking courses in the technical colleges for the Board's qualifications.

A Decade of Medical Research

In a written answer on June 17, Sir Edward Boyle gave the estimated Government expenditure on medical research in the past ten financial years as follows: 1954–55, £5·5 million; 1955–56, £6·5 million; 1956–57, £7 million; 1957–58, £8 million; 1958–59, £9·5 million; 1959–60, £10·5 million; 1960–61, £12·5 million; 1961–62, £14·5 million; 1962–63, £16 million; and 1963–64, £18·5 million. These figures include the estimated expenditure of the Health Departments, the Medical Research Council, the General Register Office, and the Air Ministry, with the estimated proportion devoted to medical research from the general grants to universities through the University Grants Committee.

U.S. Man-power Requirements in Science, Engineering and Technology

Under the title *Scientists, Engineers and Technicians in the 1960's—Requirements and Supply*, the National Science Foundation has issued a further report presenting the results of the second major investigation undertaken by the Bureau of Labour Statistics to assess these requirements in the 1960's (*NSF* 34. Pp. vii + 68. Washington, D.C.: Government Printing Office, 1964. 45 cents). In engineering, the demand for new personnel over the decade is estimated at more than 700,000, of which 165,000 represents replacement and 550,000 new demands, while the number of new entrants during the period is expected to be about 450,000. The situation will probably be particularly severe in the mid-1960's. By the end of the 1960 decade, if expenditure on the space programme levels off, and the number of engineering graduates increases more than expected, the situation may become somewhat less critical. Over the decade as a whole, the demand for engineers is expected to average about 72,000 a year compared with the projected available supply of about 45,000. In terms of numbers, the man-power situation in the sciences is expected to be less acute, though serious: the anticipated supply of 314,000 scientists, including mathematicians, being in rough balance with a projected demand of 295,000 over the decade. This assumes that the necessary college and university facilities and faculties will be available to handle the expected almost doubled enrolments in science. Scientists in some fields are likely to be in short supply throughout the 1960's, especially chemists, physicists, and medical and biological scientists and scientists with a Ph.D. degree. The demand for technicians is expected to grow at about the same rate as that for scientists and engineers, and on this basis, some 700,000 new technicians will be needed during the decade.

Encouragement for Physics in the United States

The American Association of Physics Teachers and the American Institute of Physics are very conscious of the importance of improvement of the physics teaching in schools, and they have been actively engaged for some years in directing and assisting schools in their programmes and in liaison between them and the national organizations. The "AAPT–AIP Visiting Scientists Programs in Physics", now in their fifth year, provide the stimulus of visits to high schools and institutions of higher learning and furnish valuable feed-back of information and recommendations concerning the chief local educational problems in physics. The Association's Committee on High School Awards recognizes ten high schools each year for excellence in the teaching of physics. The Institute's two booklets, *Physics in Your High School* and *Why Should You Study Physics in High School ?* encourage enrolment in high school physics. A purchase guide has been prepared to assist schools in purchasing equipment under the National Defense Education Act, and a report, entitled *Modern Physics Buildings*, is intended to contribute towards the better design of physics building facilities in schools and colleges. In order that the activities of the Association and Institute should have the greatest impact, the organizations have established the "Regional Counsellor Program" in Physics. The regional counsellors comprise a group of some fifty physicists, chosen for their competence in physics, their interest in the improvement of physics teaching, and their ability to work effectively at local level in co-operation with school and college officials to improve physics teaching. A Regional Counsellor Office has been established at the American Institute of Physics within the Institute Office of Education and Manpower to co-ordinate and support the work of the counsellors. The counsellors are unpaid, but their expenses are reimbursed. The Regional Office ensures that the counsellors receive proper recognition both locally and nationally.

Aspects of Automation

Automation at Low Cost is the title of a series of six booklets being issued during the National Productivity Year by the Information Division of the Department of Scientific and Industrial Research. The first five, dealing with counting and weighing, temperature and humidity, control of liquids, simple automation of machine tools, and control of processes, have already been published; the sixth, *Quality Control and Inspection*, is in the press. In the earlier booklets in the series, a description is given of some of the methods that a manufacturer can use to indicate and control the conditions inside his equipment, for example, the temperature of a furnace, the level of a solution in a boiler, the humidity in a drying chamber, the rate of flow of liquid into a tank, or the weight of material being added to a mixing vessel. Booklet No. 5 deals with processes in which several properties must be measured and controlled, either sequentially from stage to stage or simultaneously (*Control of Processes*. Pp. 16. London: Information Division, Department of Scientific and Industrial Research, 1963). The intention is to show to the small manufacturer some of the ways in which he can obtain the benefits of automation in his batch-production work, and that any capital expenditure on the introduction of automation would be recovered within a few years.

Journal of Medical Entomology

Volume 1, No. 1, of a new journal entitled *Journal of Medical Entomology* made its appearance in April 1964 (Pp. 1–118. Honolulu, Hawaii: Entomology Department, B. P. Bishop Museum, 1964. Published quarterly. Subscription rates: Annual subscription 10 dollars per volume to institutions and dealers; 7 dollars to individuals). It is edited by J. L. Gressitt, supported by an editorial committee widely distributed round the world, and will publish papers dealing with all phases of medical entomology and medical acarology, including systematics of insects and mites of importance in public health and in veterinary medicine. Articles exceeding one page in length are subject to a page charge of 12.50 dollars per printed page. Part 1, which runs to 117 pages, is well printed and produced (in double columns); the contributors are just about as widely distributed geographically as they could be; and the sixteen papers deal with taxonomy of mites, ticks and flies, the physiology of mosquitoes, the isolation of viruses from mosquitoes and ticks, the incidence of filariasis, and methods for mosquito surveys.

Abstracts of Papers on Radio Engineering

With the view of assisting in the general problem of the retrieval of scientific information, the British Institution of Radio Engineers has periodically published abstracts of papers which have appeared in its *Journal*. The first booklet of such abstracts was issued in 1955 (*Nature*, 176, 381; 1955) and the seventh edition has recently become available (*Abstracts of Papers published in the Journal of the British Institution of Radio Engineers*. 1952 to 1963 inclusive. Seventh edition. Pp. viii + 108. London: Institution of Electronic and Radio Engineers. 1963. 10*s*. 6*d*.). This contains 885 abstracts of papers, articles and reports published in the Institution's *Journal* during the twelve-year period 1952–63 inclusive. The abstracts are arranged according to the Universal Decimal Classification System with alphabetical subject and author indexes. Abstracts and references to reports of the Institution on technical and educational matters are included under appropriate headings, as well as editorial articles discussing matters of general and scientific interest. The completion of these abstracts to 1963 is very appropriate, since the name of the publishing body has recently been changed to "The Institution of Electronic and Radio Engineers". This seventh edition of the *Abstracts* is bound in stiff-paper covers with a colour reproduction of the Institution's armorial bearings. In order to avoid confusion in the published literature, the *Journal* of the Institution will retain the title *The Radio and Electronic Engineer*, which was adopted in January 1963.

Blakeney Point and Scolt Head Island

Blakeney Point and Scolt Head Island, edited by J. A. Steers (The National Trust, London, 1964. 5*s*.), is a new guide which replaces one published in 1952. It includes a description of the physical features of the area by Prof. Steers, who also edited the whole work. The botany and plant ecology were dealt with by the late Prof. F. W. Jane and Dr. D. J. B. White. There is an article on the bryophytes by Dr. E. Lodge, and on the insects, marine animals and mammals by Mr. E. A. Ellis. Prof. Jane also wrote the chapter on birds. The book should be invaluable to visitors to these two reserves; it is also a useful introduction to those interested in coastal ecology generally.

Mechanisms of Carcinogenesis

"In spite of all our deficiencies in knowledge, I believe we are now in prospect of a comprehensive synthesis in understanding of the means of action of chemical, physical, viral and indeed purely genetic carcinogenic influences." These brave words were written recently by Prof. Alexander Haddow in his introduction to a recent issue of the *British Medical Bulletin* devoted to "Mechanisms of Carcinogenesis—Chemical, Physical and Viral" (20, No. 2; May, 1964. London: The British Council. 30*s*.). Similar statements in the past have been premature, but the thirteen review articles that he is introducing give Prof. Haddow some justification for his optimism. Because carcinogenic substances are so diverse they must operate by biochemical routes of great variety, but all the agents by their devious routes appear to lead to deletions of genetic material with loss of the in-built controls of the normal cell. He feels that in time these processes can be elucidated with chemical precision to reveal the differences, on the cytogenetic and molecular levels, between normal and cancer cells. Chemical carcinogens have received most attention and there are contributions on the probable modes of action of the biological alkylating agents, the carcinogenic lactones, nitroso compounds, the aromatic amines, the polycyclic hydrocarbons and various natural and metallic substances other than the radioactive metals. Articles on the tumour-producing viruses stress the wide physical, chemical and biological differences among them and indicate that the mechanisms by which they act may be equally varied. The relevance of such investigations to cancer in man has acquired new importance from the recognition that a type of cancer of Africans (the Central African lymphoma, or Burkitt tumour) may well be caused by a virus. Other contributions deal with immunological factors in carcinogenesis and with radiation carcinogenesis.

U.K. Courses in Nuclear Sciences, 1964–66

The Science Department of the British Council has compiled *List* No. 8 (May 1964) of *Nuclear Studies*. The catalogue is primarily a guide for overseas students wishing to undertake specialized formal training in nuclear science in the United Kingdom. Only full-time courses, generally of one week or more in duration, are listed. Information provided includes notes on each of the courses and the institution at which it is held and also the fee and qualifications required for participation. While most of the postgraduate courses listed deal solely with nuclear science, there are a few more general courses with a substantial content of advanced nuclear science. A science or engineering degree is usually necessary for admission, and courses for non-graduates deal solely with nuclear science. The *List* has unavoidably appeared too late for application to be made for many of the courses for the academic year 1964–65. It serves, however, to direct enquiries about future courses to appropriate institutions in time for 1965–66. Copies of the *List* and further information can be obtained from the Science Department, the British Council, 59 New Oxford Street, London, W.C.1.

Royal Statistical Society

At the annual general meeting of the Royal Statistical Society on June 17, Mr. S. P. Chambers was elected president for the ensuing year. Mr. B. P. Emmett, Miss S. V. Cunliffe and Dr. J. A. Heady were elected honorary secretaries and Mr. C. T. Saunders was re-elected honorary treasurer. Prof. G. E. P. Box, professor of statistics in the University of Wisconsin, was awarded the Society's Guy Medal in Silver.

University News: Bristol

The following appointments to lectureships have been announced: Dr. S. M. Anstis (psychology); Dr. A. P. Cox (physical chemistry); Dr. M. Flower (mathematics, with the Computer Unit); Dr. P. L. Goggin (inorganic chemistry); Dr. J. Malos (physics); D. H. Peregrine (applied mathematics); M. J. R. Shave (mathematics, with the Computer Unit).

East Anglia

Dr. S. F. Mason, reader in chemistry at the University of Exeter, has been appointed professor of chemistry in the School of Chemical Sciences.

Leeds

Dr. H. L. Price, senior lecturer in mathematics, has been appointed as professor of mathematics. The following appointments to lectureships have been made: Dr. H. Hassall (biochemistry); T. F. Preece (agricultural botany); Dr. G. H. Smith (agricultural chemistry).

Southampton

Prof. Kenneth Mather, professor of genetics in the University of Birmingham since 1948 and Pro-Vice-Chancellor and Vice-Principal since 1960, has been appointed to succeed Dr. D. G. James on his retirement from the office of Vice-Chancellor of the University at the end of the session 1964–65. He was born in 1911 and was educated at Nantwich and Acton Grammar School and the University of Manchester. From 1934 until 1937 he was a lecturer in the Galton Laboratory in University College, London, and during 1937 and 1938 he was a Rockefeller Research Fellow at the California Institute of Technology and Harvard University. From 1938 until 1948 Prof. Mather was head of the Department of Genetics at the John Innes Horticultural Institution. He was a member of the Agricultural Research Council from 1949 until 1954 and from 1955 until 1960.

Announcements

Prof. Erwin Chargaff, professor of biochemistry in Columbia University, New York, has been awarded the 1963 Charles Léopold Mayer Prize of the Paris Academy of Sciences, for his work on nucleic acids.

Mr. A. Herzka, director of Pressurized Packaging Consultants, Ltd., London, has been elected president of the Society of Cosmetic Chemists of Great Britain for 1964–65.

The third European regional conference on "Electron Microscopy" will be held in Prague during August 26–September 3. Further information can be obtained from the Organizing Committee, Third European Regional Conference on Electron Microscopy, Albertov 4, Prague 2.

A conference on "Recent Advances in Activation Analysis" will be held at the University of Glasgow during August 27–28. Further information can be obtained from Dr. J. M. A. Lenihan, 9–13 West Graham Street, Glasgow, C.4.

A symposium on "High-Energy Electrons", organized by the European Association of Radiology, will be held in Montreux during September 7–10. Further information can be obtained from Dr. P. L. Cova, Casa di Cura S. Ambrogio, Via Faravalli 16, Milan.

The ninth international conference on "Low Temperature Physics", sponsored by the International Union of Pure and Applied Physics, the Ohio State University and the Battelle Memorial Institute, will be held in Columbus during August 31–September 4. Further information can be obtained from Dr. J. G. Daunt, Department of Physics, Ohio State University, Columbus, Ohio.

An international conference on "Microwaves, Circuit Theory and Information Theory" will be held in Tokyo during September 7–11. The programme will include sessions on: microwave theory and techniques and electron devices; microwave antennæ and propagation; microwave communication systems; circuit theory; information theory. Further information can be obtained from Dr. K. Morita, c/o The Institute of Electrical Communication Engineers of Japan, 2–8 Fujimicho, Chiyodaku, Tokyo.

Errata. In the communication entitled "Enolase and Fluorophosphate" by Sir Rudolph Peters, M. Shorthouse and L. R. Murray, which appeared on p. 1331 of the June 27 issue of *Nature*, for hydrolase in line 6 read hydratase; Table 1, lines 7 and 8, for FPO_3^- read $FPO_3^=$; line 2 of the final paragraph, for K_2PO_3 read $K_2F.PO_3$; in ref. 4, for Ochos read Ochoa.

THE AUSTRALIAN DEFENCE STANDARDS LABORATORIES

THE annual report of the Department of Supply of the Australian Defence Standards Laboratories, Maribyrnong, covering the period July 1, 1962–June 30, 1963*, mentions that a joint unit with the U.K. Ministry of Aviation has been set up to investigate the causes of deterioration of materials in tropical environments. The main laboratory for this purpose is near Innisfail, where 'hot-wet' conditions prevail, and a second laboratory is at Cloncurry in western Queensland, where the conditions are 'hot-dry'. Other sites, such as the marine site at Clump Point near Innisfail, will be used as required.

"Operation Blowdown", planned by the Australian Army and the Laboratories in 1961 in order to obtain data for military importance concerning the effects of a large explosion occurring in a tropical rain forest, was expected to culminate in July 1963 by the explosion of some tens of tons of trinitrotoluene at a height of 140 ft. above the ground in the rain forest area at Iron Range, Cape York Peninsula, 320 miles north of Cairns. The scientific tasks undertaken by the Laboratories included: the assembly of the explosive charge and its detonation; measurements of blast wave using pressure gauges with high speeds of response; measurements of tree strain and the investigation of displacement hazards to articulated dummies representing troops; and the assessment of damage to the forest as a whole.

In the Physics Division the work on the detection by an electron spin resonance spectrometer of the defects produced in polymethyl methacrylate by irradiation by γ-rays was extended to include the effect of a red dye, commercially incorporated in 'Perspex', as used in radiation dosimetry. The dye does not affect the free radical spectrum of the substrate, but gives rise to an additional signal. A wide-line nuclear magnetic resonance spectrometer was used to make a general survey of the resonance of nitrogen-14 nuclei in a variety of compounds, including formamide and nitrophenol. Cobalt complexes, irradiated beryllium oxide and resonances in oxygen, aluminium, chlorine, titanium and mercury were also investigated. From measurements of the anisotropy of the electrical conductivity of silicon for high electric fields at lattice temperatures of 77° K and 300° K, the temperatures of the hot electrons in the normally equivalent valleys were deduced as a function of the electric field.

The electronic counting of optical interference fringes is regarded as a promising method for the improvement in high-precision measurements of length, and equipment of this kind for the measurement of lengths up to 2 in. to an accuracy of 1 in 10^6 has been recently installed in the Physics Division. It is to be used for the standardization of about 900 sets of standard gauges. A method for the calibration of analytical weights using the built-in weights of a direct-reading balance as standards has been developed. The uncertainty in the values obtained is less than the precision of the balance, and thus the application of the method will enable the majority of chemical laboratories to standardize their own analytical weights to a high order of accuracy. The Division has taken an active part in the drafting of specifications for the range of 'Radiac' (radiation indicating and computing) instruments for use by the Australian armed services and civil defence organizations. The instruments include pocket quartz fibre dosimeters, β-γ Geiger counter contamination meters, and ionization chamber survey meters.

As part of the Chemistry Division's programme of elucidation of the molecular structure of organic compounds, the nitrogen–hydrogen stretching frequencies in a number of primary and secondary amines and amides have been determined. The results indicate that the apparent splitting of the first overtone symmetric amine stretching band arises from a combination frequency and not, as others have suggested, from the tunnelling through an energy barrier or the presence of rotational isomers. Investigations using electron impact in a mass spectrometer have shown that, while β-bond cleavage is the principal mode of fission in both aliphatic cyanides and iso-cyanides, the iso-cyanides exhibited in addition markedly greater α-bond cleavage and hydrogen rearrangement. The investigation of the effect of activation temperature on the properties of chemically pretreated brown coals has been completed. New methods for the determination of a number of atmospheric contaminants at the maximum allowable concentration for continuous exposure have been developed. The investigation of various factors which could influence the oxygen yield in electro-deposited chromium by the Adcock method has shown that, for material containing oxygen of the order of 0·1 per cent or higher, the preliminary heat treatment as required by the Adcock method significantly reduces the yield by the vacuum fusion method. Research on the photo-conductivity of zinc oxide and zinc oxide–resin mixtures has been carried out in order to explain phenomena associated with the xerographic reproduction. It has been confirmed that the chemisorption of oxygen on the surface of zinc oxide microcrystallites is an important factor in the mechanism of the dark and photo-conductivity of zinc oxide and that photoconductivity decay follows an Elovitch type of chemisorption equation. Many other factors, including the temperature, pressure, and the presence of water vapour and gaseous ions, also affect the conductivity.

The main interests of the Metallurgy Division have been, as formerly, the methods of processing chromium and chromium alloys, and measurements of their ductility, strength and creep; the abrasion of metals, including the examination of magnesium oxide particles suitable for metallographic polishing, and of the dislocation arrays produced in germanium by deformation at room temperature; and the long-term stability of nickel-base thermocouple alloys.

The annual report lists the various personnel of the Laboratories and their status, and gives details of the publications by members of the staff during the year under review. The staff numbered 724 on July 1, 1962, and 730 on June 30, 1963. Six members of the staff were in Great Britain for all or part of the year to gain experience in special aspects of their work, and the superintendent, Dr. F. A. Fox, visited both Great Britain and the United States to study present-day trends in defence and in the management of research and development organizations.

THE AUCKLAND ISLANDS

THE Auckland Islands are a small group about 200 miles south of New Zealand. They were discovered by Captain Bristow in 1806 and visited by American, French and British expeditions in 1840; their flora was studied by Sir Joseph Hooker; and in the days of sailing ships they were the cause of many wrecks, lying as they did on the route between Australia and Cape Horn. After the opening of the Panama Canal, they were left almost deserted—except for a period during the Second World War—until they were visited by an expedition from the Australian Museum during December–January, 1962–63. A preliminary account of this expedition has been published in *Australian Natural History* (14, No. 9; March, 1964).

The main Auckland Island is about 23 miles long, and 15 miles across at its widest part, bordered by precipitous cliffs on the western side while providing fine inlets and harbours on the east. Unlike all other windswept subantarctic islands, its coastal areas are covered with a thick growth of gnarled, stag-headed trees, of southern rata (*Metrosideros umbellata*), which rise to a height of 40 ft. Below these, specimens of the Macquarie Island cabbage (*Stilbocarpa polaris*), with strong antiscorbutic properties, are conspicuous, although they have been much reduced through the introduction of sheep, goats, cattle and rabbits.

Above the rata is a dense growth of scrubland vegetation (chiefly *Dracophyllum* and *Suttonia*) difficult to penetrate, although it is interspersed with lines of tussock grass (*Danthonia* and prostrate *Coprosma*). Both winged and wingless forms of a number of Diptera and Lepidoptera were taken, along with semi-apterous ichneumons, use being made of aerial nets in the ship's rigging. A new wingless cricket (*Raphidophoridae*) was found to be abundant at night.

Along the shores a supra-littoral zone, marked by white lichen, was found to change abruptly into a mid-tidal zone of bare rock, except for scattered barnacles and limpets. In turn, this zone changed into a lower-tidal one of encrusting coralline algae and the giant kelp (*Durvillea antarctica*), to be followed by an extensive zone of red and brown algae in the sub-littoral. In the rock pools, among the cryptic fauna of small gastropods, fish and worms, the expedition discovered large numbers of the small crab *Halicarcinus planatus*, the only intertidal crab on any subantarctic island. A large red spider crab, *Jacquinotia*, dominated the shallow water; two species of nototheneid fish were taken, along with the large crab, *Leptomithrax australis*, and the edible species, *Cancer novaezealandiae*.

Along the beaches, large numbers of Hooker's sea lion (*Neophoca hookeri*) were observed, the sandy beach on Enderby Island being crowded with these animals. Yellow-eyed penguins (*Megadyptes antipodes*) and crested penguins (*Eudyptes*) were plentiful, and among the other birds observed were Auckland Island shags (*Phalacrocorax campbelli colensoi*), red-billed gulls (*Larus novaehollandiae*), Antarctic terns (*Sterna vittata*), giant petrels (*Macronectes giganteus*), the sooty albatross (*Phoebetria palpebrata*), the southern skua (*Stercorarius lonnbergi*), prions (*Pachytila desolata*), diving petrels (*Pelecanoides urinatrix*), sooty shearwaters (*Puffinus griseus*), and white-headed petrels (*Petrodroma lessoni*). Of special ornithological interest were the large numbers of the Auckland Island flightless duck (*Anas aucklandica*) on Ocean and Ewing Islands.

But the expedition's most striking experience was a visit to a breeding colony of the southern race of the royal albatross (*Diomedea epomophora*), which is held to be the largest of all albatrosses, with a wing span of 11·5 ft. and a weight of 25 lb. This bird is known to nest only on Auckland and Campbell Islands, Taiaroa Head on the South Island, New Zealand, and on the Chatham Islands east of New Zealand.

RESEARCH INTO RESEARCH

DURING January–March a seminar was held in Stockholm to stimulate studies on research in social sciences. This seminar was arranged by the Academy of Engineering Sciences and supported by the Social Science and Technical Research Councils. Dr. Stevan Dedijer from the Sociological Institute of the University of Lund led the work. About half the thirty delegates were young social scientists from the universities. The others came from the Ministries and Research Councils, and from certain large industrial firms and research establishments.

The seminar met in Stockholm for two days every other week, making a total of 10 days. During the intervals, each delegate worked on his individual problem. The programme consisted of some twenty lectures, with discussions. The rest of the time was devoted to discussing the delegates' projects and progress reports.

Visitors from overseas who addressed the seminar included: Dr. Charles Kidd, head of the office for International Research at the U.S. National Institutes of Health, who spoke on "Research, Universities and the Government in the United States"; Dr. Stephen Toulmin from the Nuffield Foundation in London, who gave a stimulating lecture on "Science as the Focus of Academic Study"; Chris Freeman from the National Institute of Economic and Social Research in England, who reported his penetrating investigations into the importance of innovations in the plastics industries of different countries; and Jean Jacques Salomon from the Secretariat of the Organization for Economic Co-operation and Development, Paris, who spoke on "Science and Foreign Affairs in Europe". Almost all the leading Swedish research administrators gave lectures to the seminar. Each aired his own views on activities in different areas of research and on the selective approach necessary in a country of Sweden's size.

Subjects which the delegates considered, and which will be included in the collected essays when they are published, are: methodological problems in connexion with research statistics; the Government budget process in the fields of university research and education; an investment calculus on research and development projects in Swedish industry; civilian utilization of results emanating from defence research and development in Sweden; the ageing of research workers; the development of the theory of planning of science.

The seminar was a bold experiment, but one which, in retrospect, appears to have succeeded in its essential aims. The primary object was to pin down linguistic usage in connexion with research, so as to be able to attack clearly defined problems within various disciplines of the social science. A number of the investigations initiated by the seminar may clearly be of immediate relevance to Swedish research policy. The essential gain, however, is that young research workers have had their attention directed to the vital tasks connected with the social relations of science. Increased knowledge is needed in this field in order to weigh the value of different research projects in the industrial countries and to build up a research apparatus in the developing countries.

Social science investigations of numerous aspects of 'research' were started by English scientists in the 'thirties. That these studies did not lead further was due largely to ideological disagreement on the planning of science. To-day the chances of success are better, but occasional reflexions on the vital importance of this field will not suffice. What is needed is much hard work by a great many competent persons over a prolonged period.

SVERKER GUSTAVSSON

ADVANCEMENT OF SCIENTIFIC EDUCATION IN SCHOOLS

THE final report of the Industrial Fund for the Advancement of Scientific Education in Schools* is a brief record of a creditable episode in the history of education in the United Kingdom and Northern Ireland, which has now come to an end. The Fund was established in 1955, mainly on the initiative of Lord Weeks, Sir Alan Wilson, Mr. J. Oriel and Mr. G. Courtauld. Its object was to give a boost to the supply of scientists and technologists. Contributions were received from 141 industrial concerns, and the total sum accumulated amounted to £3,211,035. From this sum grants amounting to £2,640,500 were made to 210 schools for the renovation and extension of buildings for science teaching, and 129 schools received assistance for obtaining apparatus. Among the smaller items, a sum was set aside for the publication of a book on the planning and equipment of laboratories, based on experience acquired through the Fund; seven schools were given an engine test bed; and a special grant was allotted to Malvern College where, through aid provided by the Nuffield Foundation, new approaches are being made to the teaching of physics. Assistance was limited to independent and direct-grant schools for boys and girls, since maintained schools are the concern of the Government and Local Education Authorities; throughout the duration of the scheme interest was concentrated on the 'exact' sciences, so that the teaching of biology benefited only indirectly.

In attempting to assess the success of the scheme it is not possible to arrive at precise conclusions because of the interplay of a variety of factors. But one point not mentioned in the report is that the Fund must have been a great boon to the schools concerned in a post-war period of economic and personal austerities. Since 1955, the number of sixth-form members specializing in mathematics and science has greatly expanded; it is now common practice for all boys to be taught some science before taking the Ordinary Level Examination of the General Certificate of Education, and many schools have organized courses in science for arts specialists.

Only in the fourteen girls' schools which received grants have the results been disappointing. In them, staffing may have been a more difficult problem than lack of facilities; and apart from medicine and its associated services, girls and headmistresses alike do not look favourably on careers in science. Yet the few girls who do take science at the Advanced Level of the General Certificate of Education do well in it and particularly well in biology.

Other questions are posed by the report. In some boys' schools the "express line" of preparation for the Ordinary Level Examination of the General Certificate of Education is producing an increasing number of boys spending a third year in the sixth form, which would seem to be undesirable. Again, in recent years arts specialists have been increasing about twice as fast as specialists in science; in fact, recently in the larger public schools the number of science specialists has tended to fall, suggesting that science is not appealing to some of the most able boys. That in turn may have some relation to the limited amount of science being taught in preparatory schools, although in them there has been some improvement over the past few years. Finally, to the credit of the Fund it can be said that the standard of accommodation for teaching science which it provided was higher than that envisaged by the Ministry of Education in its *Building Bulletin* No. 2A, 1954, while the standard of equipment in maintained schools continues to give grounds for concern in relation to the place of science in the modern world and the extent to which teachers become discouraged and frustrated by present conditions.

ANISOTROPY OF FRICTION IN CRYSTALS

By DR. F. P. BOWDEN, C.B.E., F.R.S., DR. C. A. BROOKES and A. E. HANWELL

Laboratory for the Physics and Chemistry of Solids, Cavendish Laboratory, University of Cambridge

EARLIER experiments in this laboratory have shown that the friction of diamond is dependent on the crystallographic direction of sliding[1-3]. With a diamond slider (of constant orientation) sliding at low speed on the cube face of a polished diamond the coefficient of friction was $\mu = 0{\cdot}15$ when sliding in the [100] direction (parallel to the cube edge) and $\mu = 0{\cdot}05$ in the [110] direction (diagonal to the cube edge). Frictional anisotropy has also been observed on other crystals, for example, sapphire[4] and copper[5].

Magnesium oxide. We have recently examined the frictional behaviour of single crystals of magnesium oxide. This is a convenient crystal since it cleaves readily on the (001) face to give a flat surface and the techniques for examination by chemical polishing, dislocation etching and electron microscopy are well established. With a hemispherical slider moving at low speed (0·1 mm/sec) on a cleaved face in air under a load of 30 g the coefficient of friction was $\mu \simeq 0{\cdot}2$ and appreciable plastic deformation occurred beneath the surface of the crystal. This is illustrated by Fig. 1. There are two major features revealed by this photo-micrograph. First, the processes of fracture which govern the formation of wear debris occur both on and beneath the surface. Secondly, slip has taken place predominantly on those (110) planes which intersect the deformed surface at 45°, although some slip on those (110) planes at 90° to that surface is revealed. The maximum shear stress, under these conditions, is at a point below the surface and it is from this region that the dislocation loops originate and multiply. Similar deformation has been observed under conditions of rolling friction[6].

A crystal of magnesium oxide exhibits a marked anisotropy in its mechanical properties. Measurements of hardness, for example, show that this is very dependent

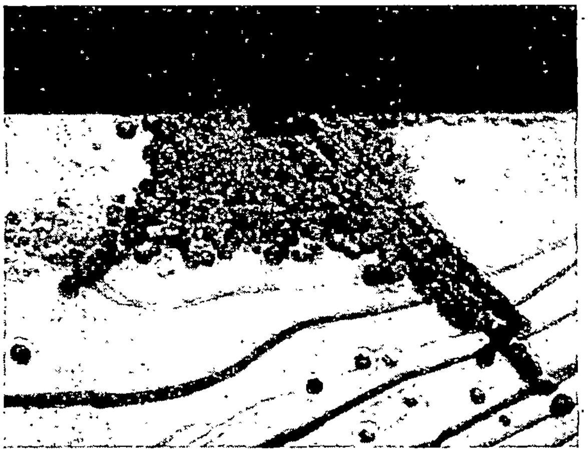

Fig. 1. Cross-section of friction track on magnesium oxide crystal showing extensive bulk plastic deformation and sub-surface cracking (etched. × c. 330)

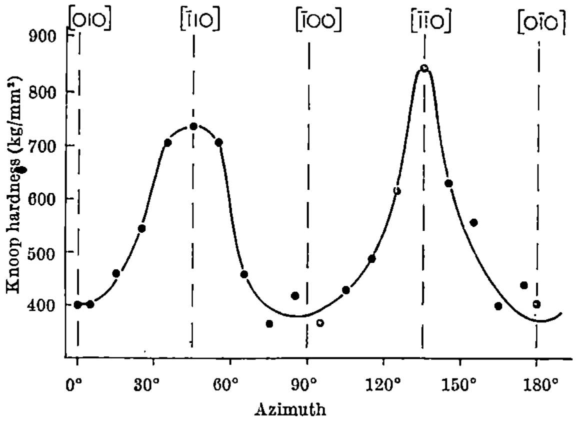

Fig. 2. Knoop hardness as a function of crystallographic orientation on a magnesium oxide cleavage face

on crystallographic direction. The (001) face of a freshly cleaved magnesium oxide crystal was indented with a load of 500 g in a microhardness apparatus using a Knoop indenter. The long axis of the indentation was measured and the results (Fig. 2) show that the hardness of the crystal in the [100] direction is about half that in the [110] direction. In the initial friction experiments a magnesium oxide slider was used. The contacting surface for both slider and crystal was (001). Various measurements were carried out in which the crystallographic orientation of both slider and crystal were varied. Some anisotropy of friction was observed but for a flat slider or one with a large radius of curvature the effect was small and not reproducible.

It is a convenient approximation to regard the frictional force F between sliding solids as being made up of two parts: the force required to shear the adhering junctions in the regions of surface contact, and the force P required to deform the underlying solid. We may write $F = As + P$, where A is the real area of contact, s the shear strength of the contact regions and P is the deformation term[7]. With an elastic solid P may be due mainly to elastic hysteresis loss[8], but if plastic flow occurs it will represent the force to produce bulk deformation or to drag the surface irregularities through the solid and to plough out a track.

In order to determine the significance of the P term, friction experiments were made on magnesium oxide crystals using diamond sliders of different shape. When the diamond slider was a very wide-angled cone (> 120°) it was found that the friction was low (that is, $\mu \simeq 0·2$ over a range of loads between 10 and 350 g), there was little surface damage and the friction was independent of the crystallographic direction of sliding. When cones of smaller angle (that is, 120°, 105°, 90° and 60°) were used, two distinct friction régimes were observed (Fig. 3). Below a critical load the behaviour was similar to that observed with a wide-angled cone, but above this load the friction and surface damage were considerably increased. The friction was then markedly dependent on the crystallographic orientation of the magnesium oxide crystal. It was much higher when sliding in the soft [100] direction ($\mu = 0·55$) than in the hard [110] direction ($\mu = 0·18$) (Fig. 4). The critical load necessary to produce this anisotropy was dependent to some degree on cone angle, decreasing with decreasing cone angle, but usually lay between 20–50 g. Examination of the friction tracks made in the high friction régime showed that they were much wider and deeper in the soft [100] direction than in the hard [110] direction. These observations are illustrated by Figs. 5*a* and *b*. Our experiments show that a critical amount of sub-surface deformation in the magnesium oxide was necessary in order to give anisotropic values of friction, that this anisotropy is associated mainly with the forces necessary to plough out a track in the crystal, and to produce plastic deformation and cracking of the crystal underneath the surface.

Diamond. Having ascertained that well-defined and reproducible frictional anisotropy could readily be observed in magnesium oxide, and that this phenomenon was due primarily to penetration of the surface and to the deformation component of the frictional force, the investigation was extended to diamond surfaces.

Experiments were carried out using the conical diamond sliders of the previous experiments. The lower specimen was a mechanically polished (001) diamond surface. The results in Fig. 6 show that, as with magnesium oxide, the

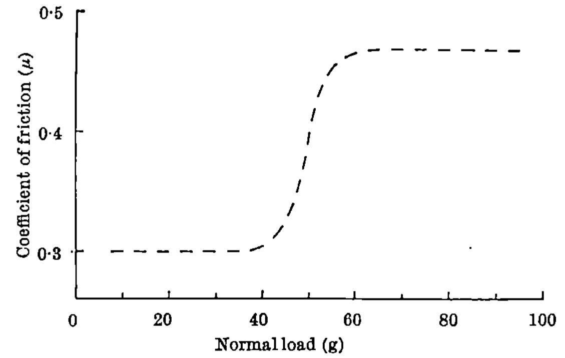

Fig. 3. Variation of coefficient of friction with normal load for a 120° conical slider on a (001) magnesium oxide surface. Anisotropy is only observed in the high friction régime

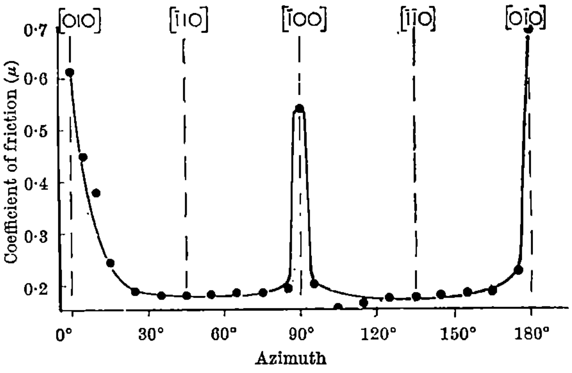

Fig. 4. Relationship between crystallographic direction and sliding friction for a sharp conical slider on (001) magnesium oxide surface

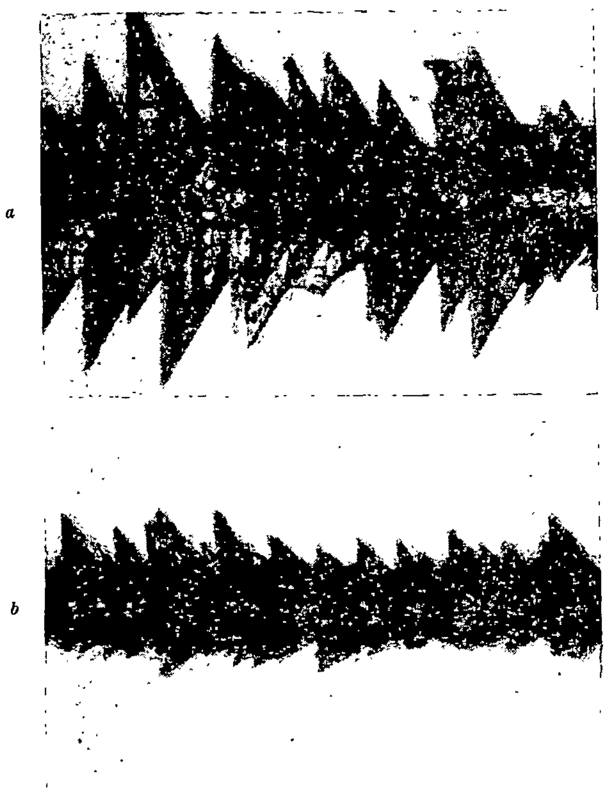

Fig. 5. Damage caused on (001) magnesium oxide by sliding in: (a) high-friction [100] direction; (b) low-friction [110] direction. Direction of sliding right to left (× 400)

amount of frictional anisotropy on this cube face increases with the sharpness of the conical slider. For example, using a 60° cone the friction increased by a factor of 3 when changing from a [110] direction of sliding to [100], and this factor is in agreement with earlier work[1,2]. However, when using a blunter cone (170°) the anisotropy in friction was only just detectable. At the load used in these experiments (130 g) no apparent damage could be detected by optical microscopy. In order to compare the deformation in the high and low friction directions, the experiments were repeated at a load which was sufficient to cause permanent damage to the diamond surface (350 g). The frictional anisotropy was similar to that observed at the lower load and the subsequent damage to the diamond cube surface is shown in Figs. 7a and b. When sliding in the high friction direction [100] considerable cracking was observed and, using the optical microscope, the track depth was estimated as about 4μ. The low-friction direction [110] produced less damage and this was very superficial. If a 'flat' diamond with a rough surface were used as a slider, it behaved in a manner similar to a sharp cone and showed the typical anisotropy of friction and of damage. These observations indicate that, as in the magnesium oxide experiments, the high friction directions are those allowing the deepest penetration by the slider (or the surface irregularities on it) and maximum deformation and cracking of the bulk crystal.

These experiments were carried out in air so that the crystal surfaces are contaminated by adsorbed gas. We have also measured the friction of diamond sliding on itself and of magnesium oxide sliding on itself in very high *vacuo* (about 10^{-10} torr) so that the surfaces are clean[9]. With both crystals the friction under these conditions rises to a high value $\mu \simeq 1$ and the abrasion and sub-surface cracking are greatly increased.

Abrasion of the crystals. Frictional forces play a major part in the abrasion of brittle solids so that we may expect the abrasion to be greatest in the direction where the friction is a maximum. With both magnesium oxide and with diamond sliding in air the high friction direction corresponds to the direction of greatest surface penetration and sub-surface damage. Magnesium oxide is brittle compared with a metal but it is, of course, capable of marked plastic deformation (Fig. 1). It is apparent that the frictional stresses produce brittle fracture due both to easy cleavage on the {100} and to dislocation interaction on the {110}. The relative extent of these will, of course, depend on external conditions such as the temperature of the crystal and the speed of sliding. If the crystal is heated, either by an outside source or by friction, the deformation may become essentially plastic. The effect has already been observed with titanium carbide crystals[10].

We may expect that similar general conclusions will apply to diamond, but because of the different crystallographic properties and because plastic deformation (if it occurs at all) is very small there will be marked differences in the behaviour. However, we see again that sliding in the high-friction direction produced the greatest crystallographic cracking and abrasion of the surface, and this is accompanied by the deeper penetration of the surface by the slider or by the irregularities on it.

A standard method of abrading or 'polishing' a diamond surface is to rub it against a cast-iron lap (or 'scaife') impregnated with diamond dust. The rubbing speed may be about 10 m/sec. It is well known that certain directions along the cube face and dodecahedron surface are easier to abrade than others. (These directions would correspond to our high-friction directions.) Tolkowsky[11] explained this anisotropy of polishing as being due to a mechanical fragmentation of the diamond. He suggested that the abrasion was due to the removal of octahedral and tetrahedral fragments bounded by the {111} cleavage planes. From geometric conclusions, therefore, a blow in a [100] direction from an abrasive particle would be more effective in removing a fragment than one in a [110] direction. More recently, Wilks and Wilks[12] have developed this farther, have confirmed the anisotropy of

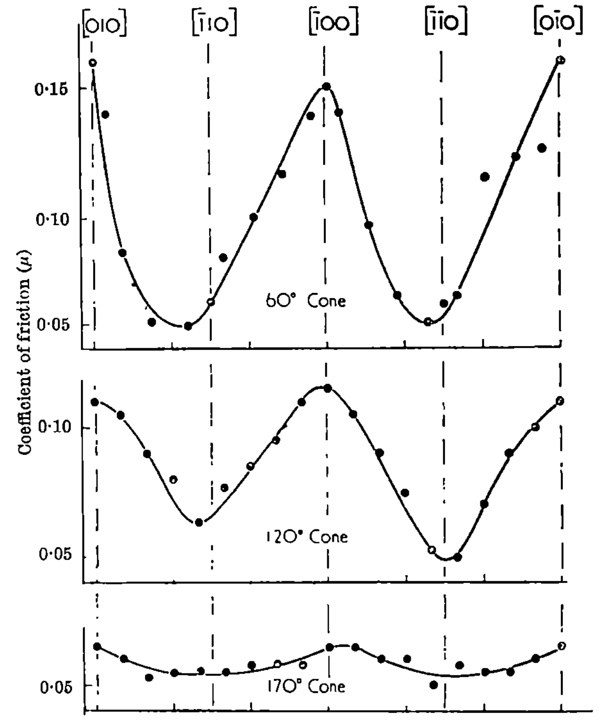

Fig. 6. Coefficient of friction as a function of crystallographic direction of sliding for various diamond sliders on a (001) diamond surface. The degree of anisotropy increases with the sharpness of the conical slider

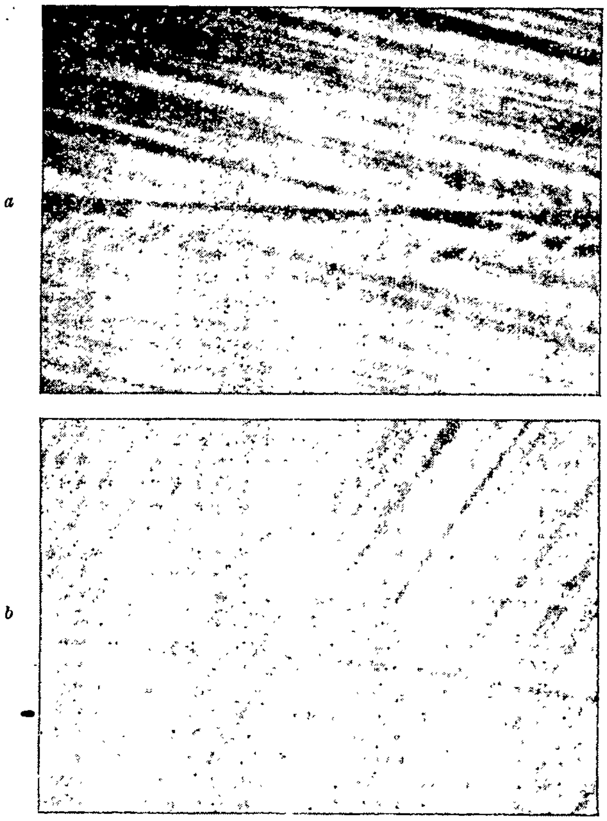

Fig. 7. Friction tracks on (001) diamond surface. (*a*) Considerable damage after sliding in high-friction [100] direction; (*b*) superficial damage after sliding in low-friction [110] direction. Direction of sliding right to left (× 400)

abrasion and have shown that the wear on a surface a few degrees off the cube face of diamond was greatly altered when the direction of rubbing was reversed.

If high sliding speeds are used, other wear mechanisms may prevail. Laboratory experiments carried out at speeds up to 800 m/sec[13,14] show that large amounts of amorphous carbon are produced. At these great speeds the surface temperature of the diamond reaches a high value so that the surface of diamond is transformed to carbon and is removed in this way. This transformation of the diamond surface to carbon occurs readily at temperatures of 1,200° C (refs. 15–17). Amorphous carbon has been observed at rubbing speeds of a few m/sec. The mechanisms of abrasion of the diamond will therefore depend on the experimental conditions and, in particular, on the speed of sliding. Under the low-speed conditions described in this paper the abrasion is primarily due to crystallographic cleavage and deformation, and this is greatest in the direction which corresponds to the greatest penetration and friction.

We thank Industrial Distributors, Ltd., for the diamonds and for a grant to the Laboratory; Owens, Illinois, for a fellowship to one of us (C. A. B.); and S. Smith and Sons (England), Ltd., for support of another author (A. E. H.).

Note added in proof. Since writing this we have seen an account of experiments on the friction of crystals by Steijn (*Wear*, 7, No. 1; 1964) which also provides some evidence that the anisotropy of friction is associated with the ploughing term.

STRUCTURE AND CATALYTIC ACTIVITY OF ALCOHOL DEHYDROGENASES

By Dr. IEUAN HARRIS

Medical Research Council Laboratory of Molecular Biology, University Postgraduate Medical School,
Hills Road, Cambridge

ALCOHOL dehydrogenase (ADH) catalyses the final step in the anaerobic fermentation of glucose to ethanol in yeast. It participates in a coupled enzyme reaction involving glyceraldehyde 3-phosphate dehydrogenase (GPDH) in which the reduced coenzyme NADH formed during the oxidation and phosphorylation of glyceraldehyde 3-phosphate is transferred to yeast alcohol dehydrogenase for the enzyme catalysed reduction of acetaldehyde to ethanol.

There is considerable evidence for the participation of sulphydryl (SH) groups in reactions catalysed by glyceraldehyde 3-phosphate and alcohol dehydrogenases (for references, see reviews by Velick and Furfine[1] and Sund and Theorell[2]), and the inhibition of alcoholic fermentation in yeast and of glycolysis in muscle by halogen acetic acids was attributed to the specific inactivation of an SH enzyme[3–5] even before the enzyme involved, namely, glyceraldehyde 3-phosphate dehydrogenase, was isolated and characterized.

The inhibition of GPDH by halogenacetic acids led to the use of iodoacetic-1[^{14}C] acid for the specific labelling of the catalytic sites in the enzyme, and to the chemical identification of these active sites as the SH groups of four cysteine residues in the primary structure of the enzyme protein. Moreover, the isolation of a unique octadecapeptide fragment containing 1[^{14}C]S-carboxymethylcysteine (^{14}CMCys) from a trypsin digest of the enzyme-inhibitor compound showed that all the reactive sites were identical and that each molecule of active enzyme (assuming a molecular weight of 140,000) was composed of four similar, if not identical, polypeptide chains each with a molecular weight of 35,000–36,000 (refs. 6–8). The active enzyme may thus be pictured as an assembly of four polypeptide chains held together by non-covalent bonds to form a quaternary 'superstructure' within which each individual chain possesses the tertiary structure which is necessary for the manifestation of catalytic activity.

Similar methods have now been applied to an investigation of alcohol dehydrogenases from yeast and from mammalian (horse) liver. The aim of this investigation has been to identify the chemical nature of the reactive sites and to determine the sequence of amino-acids around these reactive sites in the primary structure of the enzyme proteins; to correlate the number of reactive sites with the number and chemical nature of the protein chains in the two alcohol dehydrogenases, and to compare the amino-acid sequences around the reactive sites in alcohol dehydrogenases with the corresponding sequences in glyceraldehyde 3-phosphate dehydrogenases from yeast and mammalian muscle.

Alcohol dehydrogenases have been isolated as pure crystalline proteins from yeast and from horse liver (for review, see Sund and Theorell[2]). Some of the properties of the two enzymes are given in Table 1. Yeast alcohol dehydrogenase has a molecular weight of 150,000 (ref. 9). The active enzyme contains four moles of NAD (ref. 9), four atoms of zinc[10,11] and approximately 36 free SH groups[12]. The horse liver enzyme, on the other hand, appears to be approximately half the size of the yeast enzyme and its molecular weight has been reported to be between 73,000 (ref. 13) and 84,000 (ref. 14); the active enzyme contains two binding sites for NAD (ref. 14), two atoms of zinc[15] and from 24 to 28 free SH groups[16]. The yeast[17] and liver[18] enzymes are both inhibited by iodoacetic acid, but in contrast to glyceraldehyde 3-phosphate dehydrogenases inactivation of the alcohol dehydrogenases does not occur in the presence of coenzyme (NADH).

Table 1. PROPERTIES OF YEAST ALCOHOL (YADH) AND HORSE LIVER ALCOHOL (LADH) DEHYDROGENASES

Enzyme properties	YADH	LADH
Molecular weight	150,000	73,000–84,000
Bound $\overset{+}{\text{NAD}}$/NADH/mole	4	2
Bound zinc (g atoms/mole)	4	2
Total SH groups	36	24–28
Essential SH groups	4	2

Yeast Alcohol Dehydrogenase (YADH)

Reaction with iodoacetic-1[^{14}*C*] *acid.* The enzyme (C. F. Boehringer and Soehne, Mannheim) was dissolved in 0·05 M phosphate buffer (*p*H 7·5), containing 0·01 M mercaptoethanol, kept at 20° for 1 h, and dialysed against 0·05 M phosphate at *p*H 7·5 and 4° for 24 h. The enzyme solution (10 ml., containing 15 mg/ml.; 1 μmole) was incubated with iodoacetic-1[^{14}C] acid (2·7 mg; 15 μmoles) for 8 h at 4°; under these conditions the enzyme lost more than 95 per cent of its activity. Mercaptoethanol (10 μl.) was added to react with excess iodoacetic-1[^{14}C] acid; the enzyme–inhibitor compound was then reacted with an excess of non-radioactive iodoacetic acid in the presence of 8 M urea for 2 h at 25°, after which the reaction mixture was dialysed against several changes of hydrochloric acid at *p*H 3. The carboxymethylated enzyme was digested with trypsin (1 per cent trypsin, at *p*H 8·0 and 25° for 2 h) and the soluble digest was found to contain 3·8–4·4 moles of carbon-14 per mole (150,000*g*) of enzyme protein.

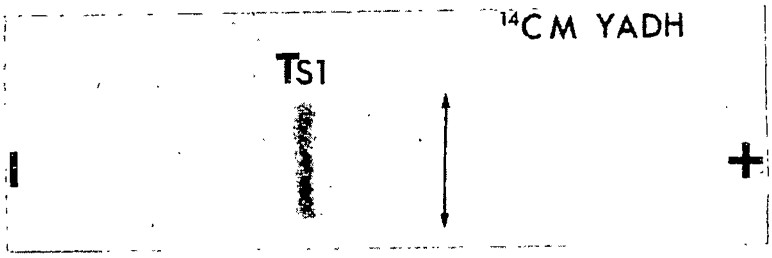

Fig. 1. Autoradiograph of peptides containing carbon-14 produced by trypsin hydrolysis of the iodoacetic 1[^{14}C] acid derivative of yeast alcohol dehydrogenase. Ionophoresis in pyridine–acetic acid buffer at *p*H 6·5

Isolation and structure of peptides containing carbon-14. In order to purify the radioactive peptide(s) a preliminary fractionation of the trypsin digest of the carboxymethylated enzyme was carried out on a column of 'Sephadex' (90 × 1·5 cm, *G*-25 grade); the column was developed with N/20 ammonia and the radioactive component (fraction TS), which emerged as a single peak, was recovered by freeze-drying. Fraction TS was next submitted to ionophoresis on paper (Whatman No. 3) in pyridine–acetic acid buffer at *p*H 6·5; the distribution of radioactivity was revealed by autoradiography and, as shown in Fig. 1, most of the carbon-14 (85–90 per cent of the [^{14}C] introduced into the enzyme protein) was found to be associated with the peptide fraction (TS1) which was 'neutral' at *p*H 6·5. At *p*H 6·2 the radioactive peptide (TS1) proved to be slightly 'basic' (that is, it migrated to the cathode side of the other non-radioactive 'neutral' peptides), and it was obtained in pure form by successive ionophoresis of fraction TS at *p*H's of 6·5 and 6·2, respectively.

Amino-acid composition and sequence of TS1. The acid hydrolysate of TS1 was submitted to amino-acid analysis and the following composition was obtained: ^{14}CMCys (1), Asp (2), Thr (2), Ser (1), Pro (2), Gly (2), Ala (1), Val (1), Leu (2), Tyr (1), His (3), Lys (1); in addition, the unhydrolysed peptide gave a positive Ehrlich test, indicating that it contained at least one residue of tryptophan.

In order to determine the amino-acid sequence of TS1 a sample (1 μmole containing approximately 10^{6} counts of [^{14}C]) was submitted to partial hydrolysis with chymotrypsin. A total of five peptide fragments was isolated by ionophoresis on paper at *p*H 6·5; the amino-acid compositions and end-groups of these peptides were determined and the partial structure of TS1 was established, as shown in Table 2. Peptide TS1 was thus shown to contain two residues of tryptophan and a total of 21 amino-acids.

The sequence around the radioactive 'label' was established by digesting peptide TS1 : C1 with subtilisin; the results of this experiment are summarized in Table 3. The sequence of peptide TS1 : C3 was investigated by stepwise degradation from the N-terminal position by the 'Dansyl–Edman' method as described by Gray and Hartley[19], and by partial acid hydrolysis. In this manner the sequence His.Gly.Asp.*Try.Pro.Leu.Pro.Thr*.Lys was obtained; the sequence in positions 16—20 could not be rigorously established by these methods and must therefore be regarded as provisional.

Table 2. AMINO-ACID COMPOSITION AND PARTIAL SEQUENCE OF PEPTIDES PRODUCED BY PARTIAL HYDROLYSIS OF PEPTIDE TS1 (YADH) WITH CHYMOTRYPSIN

↓ Indicate bonds split by subtilisin (Su).

From the results summarized in Tables 2 and 3 the amino-acid sequence of peptide TS1 from yeast alcohol dehydrogenase is established to be:

Tyr.Ser.Gly.Val.^{14}CMCys.His.Thr.Asp.Leu.His.Ala.Try.
1 2 3 4 5 6 7 8 9 10 11 12

His.Gly.Asp.*Try.Pro.Leu.Pro.Thr.*Lys.
13 14 15 16 17 18 19 20 21

Structure of yeast alcohol dehydrogenase. The inhibition of yeast alcohol dehydrogenase by iodoacetic acid has been shown to be due to a specific reaction with four residues of cysteine per mole (150,000*g*) of enzyme. The product of the reaction has been identified as S-carboxymethylcysteine and the replacement of the SH group by the S-carboxymethyl side-chain presumably leads to a conformational change in the tertiary structure which interferes with the spatial orientation of substrate and/or coenzyme molecules at the 'active centre' of the enzyme.

The identity of sequence around the four reactive cysteines shows that each molecule of active enzyme contains four identical reactive sites, and that in all probability it consists of four identical protein chains. If the results of amino-acid analysis are expressed on this basis, the following amino-acid composition may be derived for the protein monomer in YADH; Asp (29), Thr (16), Ser (22), Glu (32), Pro (14), Gly (40), Ala (34), Val (32), Met (6), Ile (19), Leu (25), Tyr (14), Phe (8), Try (6), Cys (8), Lys (24), His (10), Arg (8). This composition corresponds to a total of 346 amino-acids and to a molecular weight of approximately 36,000.

The total number of unique peptide fragments present in a trypsin digest of the carboxymethylated enzyme (approximately 30, as judged by inspection of peptide maps obtained by the fractionation of the peptide mixture by successive ionophoresis at *p*H's of 6·5 and 3·5, followed by chromatography in *n*-butanol–acetic acid–pyridine–water as a 'third dimension') agrees well with the maximum number of peptides to be expected from the number (33) of trypsin sensitive bonds (that is, bonds involving the carboxyl groups of the lysine and arginine residues) present in the protein monomer.

On this basis each individual chain contains one reactive SH group and, by binding one atom of zinc and one mole of NAD/NADH, is presumably capable of forming an independent 'active centre' within the quaternary structure of the active tetramer of molecular weight 150,000.

Kägi and Vallee[11] have already shown that removal of zinc from YADH with *o*-phenanthroline causes the dissociation of the enzyme into inactive sub-units with a molecular weight of 36,000 as determined by physico-chemical methods. On this basis the empirical formula of the enzyme was represented as $[(\text{YADH})_4\,\text{Zn}_4]\,(\text{NAD})_4$. The chemical results which I have described are in complete accord with this view and show in addition that the four sub-units are chemically identical. Removal of zinc and the accompanying dissociation of the enzyme into sub-units in the presence of chelating agents does not occur in the presence of NADH; the coenzyme also protects the reactive cysteines against reaction with iodoacetic acid[17]. These results suggest that zinc atoms are involved in maintaining the quaternary structure, and that in conjunction with the reactive cysteines they may also be concerned with the binding of substrate and/or NAD at each of the 'active centres' in the active tetramer. The chemical nature of the other side-chains which are brought into juxtaposition at the 'active centre' remains to be established. Zinc and NAD are believed to be attached at, or near to, the reactive SH group[11], and in this connexion the presence of two histidines in close proximity to the reactive cysteines in the primary structure could well provide additional ligand groups for binding zinc and/or NAD to the enzyme.

Liver Alcohol Dehydrogenase (LADH)

Reaction with iodoacetic-1[^{14}*C*] *acid.* The liver enzyme (C. F. Boehringer and Soehne, Mannheim) was dissolved in 0·1 M phosphate buffer (*p*H 7·5) containing 0·01 M mercaptoethanol, kept at 20° for 1 h and dialysed against 0·05 M phosphate at *p*H 7·5 and 4° for 24 h. The enzyme solution (8 ml. containing 10 mg/ml.; 1 μmole) was incubated with iodoacetic-1[^{14}C] acid (1·8 mg; 10 μmoles) for 12 h at 4°. The inactive enzyme-inhibitor compound was then reacted with an excess of non-radioactive iodoacetic acid in 8 M urea at 25° for 2 h and the carboxymethylated enzyme was recovered by dialysis against hydrochloric acid at *p*H 3. A sample portion (20 mg) was digested with trypsin (1 per cent trypsin, *p*H 8·0, 25° for 2 h) and was found to contain 1·8 moles of carbon-14 per mole (73,000*g*) of enzyme protein in agreement with the results obtained by Li and Vallee[18]; in a separate experiment another sample (40 mg) of the carboxymethylated enzyme was digested with chymotrypsin (1 per cent chymotrypsin, *p*H 8·0, 25° for 2 h).

Isolation of peptides containing carbon-14. The trypsin and chymotrypsin digests of the carboxymethylated enzyme were fractionated on a column of 'Sephadex' (90 × 1·5 cm, *G*-25); the radioactive components (fractions TS and CS, respectively) were submitted to ionophoresis on paper (Whatman No. 3) in pyridine–acetic acid buffer at *p*H 6·5, and the distribution of radioactive peptides was revealed by autoradiography. Most of the carbon-14 in the trypsin digest (80–90 per cent) was found in the peptide fraction (TS1), which was 'neutral' at *p*H 6·5. In the corresponding chymotrypsin digest the carbon-14 was found to be associated with the two acidic peptide fractions; 80–85 per cent was in fraction CS1 and the remaining 15–20 per cent in fraction CS2 (Fig. 2).

(*Note added in proof.* The structure of peptide TS1 from ^{14}CM-LADH has now been shown to be Met.Val.Ala.Thr. Gly.Ile.^{14}CMCys.Arg. T. K. Li and D. E. Drum (*Fed. Proc. Abst.*, No. 1934; 1964) report that the peptide which they have isolated from a trypsin digest of ^{14}CM-LADH contains Lys, Arg, Cys, Asp, Thr, Ser, Glu, Gly, Ala, Val, Ile.)

Peptide TS1 was heavily contaminated with other 'neutral' non-radioactive peptides, and in order to facilitate the purification of the radioactive moiety the mixture of 'neutral' peptides was digested further with chymotrypsin; the radioactive peptide (TS1 : C1), which was also 'neutral' at *p*H 6·5, was obtained in pure form by successive ionophoreses on paper at *p*H's of 6·5, 3·5 and 1·9. Peptides CS1 and CS2 were purified in a similar way.

Amino-acid composition and sequence of peptides containing carbon-14. The acid hydrolysates of peptides TS1 : C1, CS1 and CS2 were analysed for constituent amino-acids and were found to have the following compositions: TS1 : C1: ^{14}CMCys (1) Gly (1) Ile (1) Arg(1); CS1: ^{14}CMCys (1) Asp (2) Thr (2) Ser (2) Gly (2) Ala (1) Val (2) Leu (1) Ile (1) His (1) Arg (1); CS2: ^{14}CMCys (1) Asp (2) Thr (1) Ser (2) Gly (2) Val (1) Leu (1) Ile (1) His (1) Arg (1).

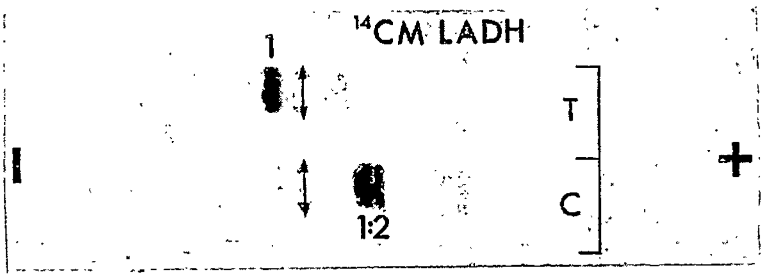

Fig. 2. Autoradiograph of peptides containing carbon-14 produced by trypsin (*T*) and chymotrypsin (*C*) hydrolysis of the iodoacetic 1[^{14}C] acid derivative of horse liver alcohol dehydrogenase. Ionophoresis in pyridine–acetic acid buffer at *p*H 6·5

When peptide CS1 was digested with trypsin it was split into two fragments: a 'neutral' radioactive peptide CS1 : T1, containing ^{14}CMCys (1) Thr (1) Gly (1) Ala (1) Val (1) Ile (1) Arg (1), and an acidic non-radioactive peptide CS1 : T2, containing Asp (2) Thr (1) Ser (2) Gly (1) Val (1) Leu (1) His (1). In a similar manner peptide CS2 was split by trypsin to give CS2 : T1, which was identical with TS1 : C1, and CS2 : T2, which was identical with CS1 : Ts.

The amino-acid sequences of these peptides were established by the 'Dansyl–Edman' procedure, as described by Gray and Hartley[19]. For example, peptides CS1 : T1 and CS1 : T2 (0·1 μmole) were each degraded in a stepwise manner, and the N-terminal amino-acids formed at each successive step were identified as their dimethylaminonaphthalene-sulphonyl ('dansyl') derivatives by ionophoresis on paper at *p*H 4·4. The results obtained are summarized in Table 4.

Structure of horse liver alcohol dehydrogenase. The major radioactive peptides present in trypsin and chymotrypsin digests of the enzyme-inhibitor compound are clearly derived from the same unique sequence of amino-acids. The two reactive sites are identified as the SH groups of two cysteines and these are shown to occur in the same sequence in the primary structure of the enzyme protein. These results show that liver alcohol dehydrogenase contains two structurally equivalent active sites and that in all probability the active enzyme consists of two identical polypeptide chains each with a molecular weight of approximately 36,000 (assuming the lower molecular weight of 73,000 (ref. 13) for the active dimer). By analogy with the yeast enzyme each chain contains a reactive SH group which, in conjunction with zinc and other, as yet unidentified, amino-acid side-chains, appears to be involved in the binding of substrate and/or NAD/NADH to each of the two 'active centres' within the quaternary structure of the active dimer.

Comparative Structures of Dehydrogenases

The amino-acid sequences around the reactive cysteines in yeast and horse liver alcohol dehydrogenases, together with the corresponding sequences in glyceraldehyde 3-phosphate dehydrogenases from yeast and mammalian muscle, are compared in Table 5. In marked contrast to GPDH'S, in which the sequences are identical, significant differences in sequence are found to occur between alcohol dehydrogenases of yeast and mammalian origin. Of particular interest is the replacement of the histidine residue (position 7) which occurs adjacent to the reactive cysteine in the yeast enzyme, by arginine in the horse liver enzyme; the histidine (position 11), five residues away from the reactive cysteine, occurs in the same *relative* position in both enzymes. If the residues in positions 6, 7 and 11 in the sequence (that is, cysteine, histidine/or arginine, and histidine, respectively) are indeed involved in the binding of zinc, then this replacement of histidine by arginine could well account for the observed differences[11] in the zinc-binding properties of the two enzymes.

Mutations which have led to alterations in sequence in the immediate neighbourhood of the reactive cysteines (that is, positions 3–9, Table 5) have clearly involved the replacement of a given amino-acid by another chemically related one; thus serine, valine and threonine in the yeast enzyme have been replaced by threonine, isoleucine and serine, respectively, in the liver enzyme. Outside this heptapeptide segment of the chain (that is, positions 1–2 and 10–16, but with the exception of histidine in position 11) the sequences appear to be entirely unrelated. It may therefore be inferred that the amino-acid side-chains in close proximity to the reactive cysteines in the primary structure cannot be altered to any appreciable extent without at the same time affecting the tertiary structure which is essential for maintaining the structural integrity of the 'active centre' in alcohol dehydrogenases.

Although yeast and liver alcohol dehydrogenases catalyse the same reaction, namely, the reversible oxidation and reduction of alcohols to the corresponding aldehydes (or ketones) in the presence of NAD/NADH, the two enzyme proteins differ considerably in amino-acid

composition and molecular weight. The yeast enzyme is a tetramer with a molecular weight of 150,000, while the liver enzyme is a dimer with a molecular weight of 73,000–84,000; the former dissociates into sub-units in the presence of metal chelating agents such as *o*-phenanthroline, while the latter does not[11]. The two enzymes also differ in their substrate and co-enzyme specifications; for example, YADH reacts more rapidly with ethanol than with higher alcohols, whereas LADH has a broader specificity, and acts on long-chain primary alcohols such as vitamin A. Thus, although the two enzymes catalyse the same basic chemical reaction, the overall pattern of metabolic events in liver is very different from the process of alcoholic fermentation in yeast. This difference in the biochemical environment and function of the two alcohol dehydrogenases is much more marked than is the case with the glyceraldehyde 3-phosphate dehydrogenases of yeast and mammalian muscle; and the extent of this biochemical adaptation seems to be reflected in the correspondingly greater chemical changes which have occurred in alcohol dehydrogenases during the evolutionary development of the respective enzyme proteins.

In spite of the considerable differences in overall chemical composition and structure which exist between the two alcohol dehydrogenase proteins the fundamental structural unit consists in each case of a protein chain with a molecular weight of about 36,000; this structural unit binds NAD/NADH and zinc and contains a reactive SH-group in a sequence which, although changed, has changed in such a way as to preserve a very similar sequence of amino-acids in the immediate vicinity of the reactive cysteines in the two enzymes.

In this respect alcohol dehydrogenases resemble the glyceraldehyde 3-phosphate[6–8], and lactic[20,21], dehydrogenases, which have also been shown to consist of sub-units with a molecular weight of 35,000–36,000. In glyceraldehyde 3-phosphate and alcohol dehydrogenases the protein chains in each individual enzyme appear to be identical; lactic dehydrogenases, on the other hand, exist in the form of isoenzymes consisting either of four identical chains or of different proportions of two dissimilar chains.

An examination of enzyme-substrate and enzyme-inhibitor compounds by methods of structural organic chemistry has led to the characterization of the protein sub-units in dehydrogenases of the glycolytic cycle. In terms of their chemical morphology dehydrogenases appear to resemble the hæmoglobins[22], and one may hope that future chemical and X-ray crystallographic investigations will lead to the elucidation of the amino-acid sequences, and of the folded three-dimensional structures of their constituent polypeptide chains. Only when this has been achieved will it become possible to provide a chemical basis for their catalytic properties. One may also look forward to tracing the evolutionary development and biochemical adaptation of these enzymes in terms of their chemical structures, and to the discovery of structural interrelationships between enzymes which couple together to promote successive steps in related biochemical processes such as glycolysis and alcoholic fermentation.

I thank Mr. R. J. A. Turner for his assistance throughout the course of this work.

BIOCHEMICAL PATHOLOGY OF ACUTE HEPATIC ADENOSINETRIPHOSPHATE DEFICIENCY*

By Prof. EMMANUEL FARBER, Prof. KENNETH H. SHULL, Dr. SAUL VILLA-TREVINO,
Prof. BENITO LOMBARDI and MOLLY THOMAS

Department of Pathology, University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania

We have been engaged during the past several years in the examination of how some cells and organs respond to the presence of ethionine, an analogue of the amino-acid methionine, so as to manifest disease at both the morphological and biochemical level. The aim was two-fold: (*a*) to investigate a model experimental disease with the hope of understanding the biochemical significance of some alterations in cellular morphology; (*b*) to examine the response of living cells, as working units, to changes in their environment leading to disease. Such information hopefully would give new insight into the mechanisms by which cells integrate some of their reactions. The examination of many such model experimental disease systems, amenable to simultaneous biochemical and morphological analysis, would appear to be essential for the ultimate understanding of the more complex natural diseases. The choice of the amino-acid antagonist, ethionine, for this type of investigation seemed an apt one, since selectivity in its effects on cells might be expected.

Ethionine, the ethyl analogue of methionine, was synthesized by Dyer[1], who observed it to be toxic in the rat. Since then, many well-defined effects have been found in several other animal species as well as in micro-organisms[2,3].

In the rat and in several other species, the oral or parenteral administration of ethionine results in characteristic and reproducible lesions in the liver, pancreas, kidney, testis and certain other organs[2,3]. Most of these changes are acute, occurring within hours or a few days; but others, such as cancer of the liver, appear only after treatment of the animal for several months. One of the main interests in this analogue, from the point of view of disease, stems from the finding that virtually all its effects, both morphological and biochemical, are readily prevented by the administration of adequate amounts of methionine. The relationship between ethionine and methionine appears to be specific, since no other sulphur-containing amino-acid or other amino-acid shows any protective effect.

---

* Substance of the Christian Herter Lecture delivered by Prof. E. Farber in New York University Medical School on April 3, 1963.

One of the earliest lesions observed in animals treated with ethionine is the rapid development of a fatty liver[4]. In this choline-resistant lesion, the lipid accumulates first in the liver cells about the periportal region of the liver lobule and afterwards involves the rest of the lobule[5]. The excess lipid is all triglyceride[6] with a fatty-acid pattern resembling that of adipose tissue triglyceride[7,8]. This suggests that the source of the fatty acids for the triglyceride deposited in the liver is the adipose tissue. The fatty liver occurs readily in female rats but either not at all or to a considerably less degree in the male[4,9]. This sex difference in the lipid accumulation appears to be a function predominantly of androgens in the male since: (*a*) ovariectomy has no effect on the occurrence of the fatty liver in the female, while orchidectomy makes the male much more susceptible; (*b*) the administration of testosterone or related compounds, especially those with potent protein sparing actions, completely protect both the female and the castrate male[9,10]. Of the many other hormonal preparations tested, only growth hormone has a similar action[10].

In addition to inducing a fatty liver, ethionine inhibits protein synthesis in the liver when measured both *in vivo* and *in vitro*[11,12]. Many liver enzymes and several plasma proteins have been found to be decreased in the ethionine-treated animal[2,3]. Again, a sex difference is evident in that the inhibition occurs predominantly or exclusively in the mature female but not in the mature male[12]. In contrast to the inhibition of hepatic protein synthesis and the induction of fatty liver, some other effects of ethionine, such as inhibition of transmethylation from methionine to choline precursors[13] or inhibition of the oxidation of the methyl group of methionine to formate and carbon dioxide[14], are manifest equally in both sexes. Thus, a correlation exists between the disturbance in protein metabolism and the accumulation of liver lipid[15–17]. The interrelationships between these two lesions and their dependence on a more basic alteration in ATP metabolism has recently been clarified and is the subject of this report. Some new insight into the integration of some cell functions obtained during this study is discussed briefly.

Induction of ATP Deficiency

The first major clue to our understanding of the biochemical pathology of the effects of ethionine on the liver was derived from the observations by Shull[18] on hepatic glycogen phosphorylase. He found that the activity of this enzyme was decreased in ethionine-treated female rats and that, of the factors known to influence its level, ATP but not 3′-, 5′-cyclic adenylic acid, when added *in vitro*, partially reversed this inhibition. This implied that the decrease in enzyme activity was secondary to some alteration in the liver ATP. This supposition was greatly strengthened by the observation that the enzyme changes could be readily prevented if adenine or ATP were administered to the animal along with ethionine. These compounds proved to be as effective as methionine. Measurement of the liver ATP concentration revealed that ethionine administration is followed by a very striking decrease in the level of hepatic ATP[11] in confirmation of a previous suggestion by Stekol *et al.*[19]. Although the decrease occurred in both male and female rats, it was about twice as large in the female as in the male.

The concentration of ATP begins to decrease within 30 min after the injection of ethionine and reaches a minimum value of about 20 per cent of the control value within 2 h (ref. 20). The magnitude of the decrease is proportional to the dose of ethionine administered up to about 0·5 mg/g body-weight. Because of this, it is possible, by administration of the appropriate amount of ethionine, to obtain a reproducible spectrum of levels of ATP in the liver ranging between the control and the minimal value. The decrease in hepatic ATP concentration is prevented by the administration not only of methionine but also of adenine, ATP, inosine and, to a lesser degree, 5-amino-4-imidazole-carboxamide and nicotinamide, but not by the injection of glycine, sodium formate, glutamine and ribose. Adenine is effective not only when it is administered with ethionine but also when administered 24 h after the ethionine, by which time morphological and biochemical lesions have been obvious for many hours.

Two suggestions by Stekol *et al.*[19,21] have been proposed to explain the effects of ethionine on ATP. In both of them, the basic explanation depends on the conversion of ethionine to S-adenosylethionine. Through the original work of Cantoni[22] and subsequent investigations of Schlenk *et al.*[23] and of Stekol, it is now well established that methionine reacts with ATP (ARPPP) to form S-adenosylmethionine (SAM) via an activating enzyme[1].

II

However, unlike S-adenosylmethionine[23], S-adenosylethionine (SAE) is not readily utilized for many transalkylations and other metabolic reactions[2,3].

(*a*) According to one suggestion of Stekol *et al.*[19], S-adenosylethionine accumulates in the tissue as a result of the activation, causing an inhibition of mitochondrial oxidation and oxidative phosphorylation, and a concomitant decrease in the rate of synthesis of ATP. Evidence in support of this thesis is the observation that S-adenosylethionine inhibits oxidative phosphorylation when added *in vitro* to mitochondrial preparations[19]. Against this interpretation, however, stand the results of several investigations[24–26] showing normal respiration and oxidative phosphorylation in isolated liver mitochondria from animals treated with ethionine in doses which produce pathological changes in the liver and elsewhere. Recent work in this Department has also shown that the administration of adenine or of an adenine-precursor many hours after the induction of severe biochemical and morphological lesions in rats will readily reverse the effect

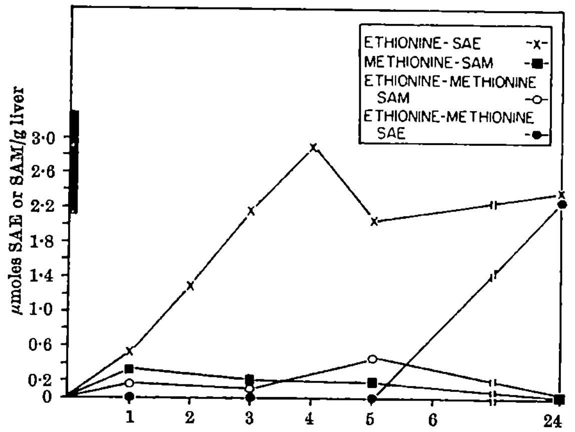

Fig. 1. Hepatic concentrations of S-adenosylethionine (SAE) or S-adenosylmethionine (SAM) following the intraperitoneal administration of ethionine (1 mg/gm body-weight) and/or an equimolar amount of methionine, as indicated in the rectangle. Note the absence of any SAE accumulation in the liver for the first 5 h after the administration of ethionine plus methionine and the high level at 24 h. The highest range of liver ATP concentration as reported in the literature and as observed in this department is indicated by the thick solid bar on the ordinate. SAE and SAM were determined chromatographically on the 15-cm column of the Spinco Moore–Stein–Spackman amino-acid analyzer

on ATP[27], a finding difficult to reconcile with this hypothesis.

(b) According to the other suggestion[21], for which there is increasing evidence, ATP decreases in the liver because it reacts with ethionine to form S-adenosylethionine at a rate faster than the cell can synthesize the nucleotide *de novo* from available precursors. Such an 'adenine-trapping effect' of ethionine was clearly shown in yeast by Schmidt *et al.*[28]. Work in our laboratory has indicated that, shortly after the administration of ethionine, one can detect S-adenosylethionine in the liver[29]. Its concentration increases rapidly with time up to about 5 h and thereafter remains at a high level for at least 24 h (Fig. 1). In the case of methionine administration, the extent of S-adenosylmethionine accumulation is considerably less and the level of this compound in the liver becomes undetectable within 24 h (Fig. 1). These observations are best explained by assuming that S-adenosylmethionine is readily used by the liver for many metabolic reactions and thus does not accumulate in large amounts. This metabolic use of SAM probably releases an adenine derivative[30] which may be re-used for ATP synthesis. In contrast, the poor metabolic utilization of S-adenosylethionine would favour its accumulation in the liver. This trapping action of ethionine would tax the liver beyond its capacity to make the adenine moiety of ATP *de novo* from the usual precursors. The efficacy of adenine in counteracting the drop in ATP would appear to be due to its rapid conversion to ATP, presumably via the adenylate pyrophosphorylase and kinase leading to ADP. and the phosphorylation of this ADP to ATP through oxidative phosphorylation. Since mitochondrial oxidation and oxidative phosphorylation appear to be normal in the liver of the ethionine-treated rat, the generation of ATP from ADP should be sufficiently rapid to maintain adequate ATP levels, even in the presence of an ATP-trapping system, providing sufficient adenine is supplied to form AMP and ADP.

Inhibition of Protein Synthesis

Since ethionine administration is followed by a rapid decrease in the concentration of hepatic ATP the question arose as to whether this decrease might be the underlying basis for the inhibition of protein synthesis[21]. All the available evidence now supports this hypothesis[20,31]. Adenine or ATP administered to an animal counteracts completely the inhibition of protein synthesis induced by ethionine. Most of the measurements of protein synthesis were made on an *in vitro* ribosome-supernatant system in which the incorporation of radioactive leucine into protein was followed. However, similar results were obtained with the incorporation of radioactive amino-acids into liver protein *in vivo* as well as with a non-isotopic method, the increase in hepatic 2-acetylaminofluorene hydroxylase activity following the administration of methylcholanthrene[20]. Furthermore, the examination of the time course of the effects of ethionine shows that the drop in ATP precedes by about 1 h the drop in amino-acid incorporation into the ribosomal system[20]. In addition, the administration of different levels of ethionine induces proportional decreases in the levels of ATP and in the degree of inhibition of protein synthesis.

Assuming then some relationship between ethionine, ATP and protein synthesis, two questions naturally arise: (*a*) How does the drop in ATP inhibit protein synthesis ? (*b*) How is the decrease in ATP related, if at all, to the induction of fatty liver or to the induction of other biochemical or morphological alterations in the liver and other organs ?

Relation of ATP to Protein Synthesis

ATP is known to play a part in protein synthesis in at least three sites: (1) the activation of the amino-acids [AA] for their reaction with transfer RNA (*s*-RNA); (2) the reaction of *s*-RNA–AA with the ribosomal components and the subsequent formation of the peptide bonds of the nascent protein, which appear to require at least two transferases and guanosine-triphosphate (GTP)[32–39], the synthesis of which is dependent on ATP; and (3) the synthesis of messenger RNA (*m*-RNA) (ref. 40) in the nucleus. The attachment of this *m*-RNA to ribosomes appears to play a vital part in the proper assembly of inactive ribosome monomers to form ribosome aggregates or polymers functionally active in protein synthesis in micro-organisms[41–47] as well as in liver[48–51] and in other mammalian cells[52–59].

All the available evidence points to the ribosomes as the major locus for the inhibition of protein synthesis in the ethionine-treated rat: (1) In the *in vitro* assay of amino-acid incorporation into protein, the use of the amino-acid activating and transferring systems and of transfer RNA from normal liver fails to influence the severe degree of inhibition observed when ribosomes from ethionine-treated female animals are used[12,31]. (2) The *p*H 5 fraction from the liver supernatant from ethionine-treated rats is just as active in activating and binding leucine, valine and methionine to transfer RNA as is the fraction from control animals[60]. (3) The presence of ATP and GTP, which are normally used in the assay system for amino-acid incorporation into protein, has no effect on the degree of inhibition[12,31].

Assuming that the ribosome is the major site for the inhibitory action of ethionine, the ATP deficiency could affect the integrity of the ribosome itself or the synthesis or availability of messenger RNA reacting with the ribosome monomers. Since the substrates for RNA synthesis are the four nucleoside triphosphates [ATP, GTP, UTP, CTP] a large decrease in the concentration of one of them, ATP, could seriously reduce the rate of cellular RNA synthesis. There is increasing evidence that the ATP deficiency induced by ethionine does indeed inhibit the synthesis of RNA in the nucleus and that this interference with RNA synthesis may be a major way by which the decrease in ATP concentration affects protein synthesis. This suggestion is based on the following observations: (1) The administration of ethionine is followed by a striking inhibition in the extent of incorporation of ^{14}C-6-orotic acid or of ^{14}C-8-adenine into nuclear RNA[61]. This inhibition is prevented by the administration of methionine along with the ethionine. The time curve of this inhibition coincides with the time

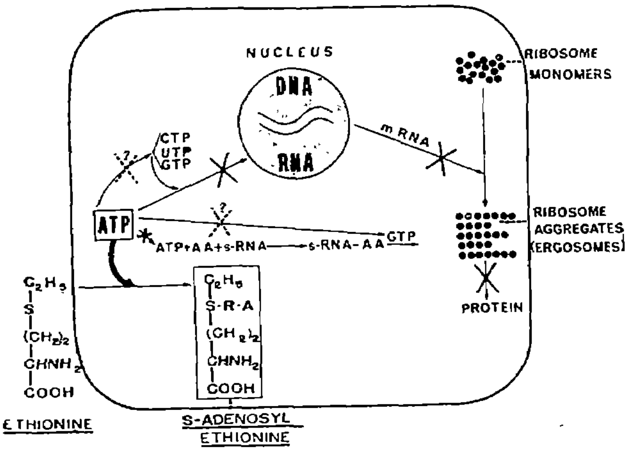

Fig. 2. Diagrammatic representation of the liver cell showing the known sites where ATP is directly involved in protein synthesis and the probable sites of inhibition of protein synthesis in the ethionine-treated female rat (X). Other possible sites of inhibition not yet investigated are indicated by ?✕. CTP, UTP, and GTP are the triphosphates of cytidine, uridine and guanosine respectively

curve of the decrease in liver ATP and precedes by about 1 h the time curve of the decrease in ribosomal protein synthesis. (2) The progressive inhibition of protein synthesis following ethionine administration is accompanied by a decrease in the number of ribosomal aggregates and a corresponding increase in the number of ribosomal monomers as observed on analysis in a sucrose gradient after centrifugation[62]. There is now increasing indication that liver ribosomal protein synthesis is dependent on the continual synthesis and availability of *m*-RNA[49]. The liver ribosomes appear to be active in protein synthesis only when combined with *m*-RNA to form active organized aggregates which may contain from two to twenty or more ribosomes. The liver ribosome pattern from the ethionine-treated female[62] is virtually identical to that observed following actinomycin *D* administration to the rat[49] and is different from that following puromycin injection[62]. Since actinomycin appears to affect ribosome aggregation and protein synthesis by inhibiting DNA-dependent RNA synthesis[63-70], it appears probable that ethionine affects ribosomal protein synthesis and ribosomal assembly basically in a similar manner by interfering with *m*-RNA synthesis (Fig. 2). This is in contrast to puromycin, which seems to act at the level of the ribosome itself[71] and to interfere with the formation of the peptide bonds of the nascent protein[72-75].

The suggestion that the ethionine-induced ATP deficiency acts primarily on protein synthesis at the level of ribosome assembly is considerably strengthened by observations during the reversal of the inhibition of protein synthesis. Unlike the inhibition of protein synthesis by actinomycin *D* or puromycin, the ethionine-induced inhibition can be readily reversed by the administration of adenine, methionine or adenine plus methionine, even many hours after the inhibition has been in force. When this is done, there occurs a rapid progressive reassembly of the ribosome monomers to form large organized aggregates[62] which have also been called ergosomes[48]. In fact, as protein synthesis returns to normal, there occurs an unusual preponderance of the heaviest ergosomes, the significance of which is still not clear. In some animals during the immediate recovery phase, protein synthesis becomes more active than in control animals and it appeared that the presence of the heaviest aggregates correlated with this observation. However, the livers of some animals have been observed to possess a similar pattern of large ergosomes without any apparent acceleration of protein synthesis[62].

Consistent with the suggestion that the main site of interference with protein synthesis in the ethionine-treated rat is in the ribosome are the recent findings on binding of leucine-^{14}C or methionine-^{14}C to liver *s*-RNA *in vivo*[76]. Although some inhibition of formation of *s*-RNA-leucine or *s*-RNA-methionine does occur in the liver of the intact female rat injected with ethionine, this can easily be reversed within 30 min following the administration of adenine without any appreciable reversal of the inhibition of amino-acid incorporation into liver protein at this time-interval.

The present-day concept of the inhibition of protein synthesis by ethionine is portrayed diagrammatically in Fig. 2. In this figure and in the foregoing discussion, only protein synthesis in cytoplasmic ribosomes has been considered. Although amino-acid incorporation into proteins has been demonstrated in other cell organelles such as the nucleus and the mitochondria[77], nothing is yet known about the possible effects of ATP deficiency on these systems.

Relation of ATP to Fatty Liver

Recent work has shown that the administration of adenine or ATP completely prevents the accumulation of excess triglyceride in the liver when measured either chemically or histochemically[78]. The administration of ATP also effectively prevents the decrease in serum lipid levels which is so characteristic a concomitant of several forms of fatty liver[79]. Equally interesting is the observation that the administration of adenine is frequently also effective in rapidly removing the excess liver triglyceride even after it has been accumulating for 24 h (ref. 80). Thus the fatty liver appears to be related in some fashion to ATP.

The interrelationships between hepatic ATP deficiency, inhibition of protein synthesis, and the changes in liver and serum lipids which have been uncovered during these recent investigations on ethionine may offer new clues to the pathogenesis of fatty liver. It has become evident from work initiated by Recknagel, Lombardi and Schotz[79,81,82] that several forms of fatty liver, including that induced by carbon tetrachloride[82,83] and ethionine[79], are probably secondary to a block in the release of liver lipid into the plasma. According to this hypothesis[79,83,84] the liver in the ethionine-treated animal continues to take up free fatty acids (FFA) from the blood and to esterify them to triglycerides but fails to transfer the newly synthesized triglycerides into the plasma[85-88] with a resultant increase in liver triglyceride content.

Based on the correlation between inhibition of protein synthesis and the occurrence of fatty liver, it was suggested several years ago that the development of fatty liver in the ethionine-treated female was secondary to the more fundamental disturbance in protein metabolism[15-17]. Feinberg *et al.*[89] and more recently Lombardi and Recknagel[79,83], Robinson and Harris[90] and Bjornstad and Bremer[91] suggested that the link between the alterations in protein and in lipid metabolism is the synthesis of plasma lipoproteins. Since plasma lipids occur almost wholly as lipoproteins and since the liver is a probable major source for at least some lipoproteins[92-96], an inhibition of protein synthesis in the liver might interfere with the normal transfer of the lipids from the liver to the plasma. Some of these suggested relationships are illustrated in Fig. 3.

The observation that the inhibition of protein synthesis induced by ethionine is in itself secondary to a decrease in hepatic ATP concentration immediately raises the question whether the lipid accumulation and the disturbed protein metabolism might not be independent manifestations of the same basic biochemical disturbance. In this connexion, it should be recalled that Dianzani[97] several years ago suggested that the fatty liver induced by carbon tetrachloride might result from an ATP deficiency. The final answer to these important considerations cannot be

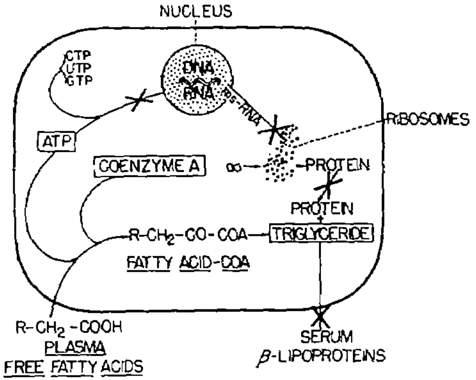

Fig. 3. Diagrammatic representation of a liver cell showing uptake of free fatty acids (FFA) and their conversion to triglyceride. Much of the triglyceride (together with other lipids not shown) is released as serum lipoproteins. The major sites of inhibition by ethionine of protein synthesis and of the release of the lipoproteins are indicated by X

given at this time. However, experiments on ethionine-treated animals given adenine after the liver has become fatty indicates the existence of a better correlation between inhibition of protein synthesis and fatty liver than between hepatic ATP and fatty liver[80]. It is, therefore, probable that the examination of the suggested relation between disturbances in protein and in lipid metabolism offers the best hope for the eventual understanding of the pathogenesis of some types of fatty liver. It is noteworthy that this hypothesis relating the induction of fatty liver to a more basic defect in protein metabolism may not only apply to the animal treated with ethionine but may have wider application to the pathogenesis of fatty liver[78] induced by some other agents such as carbon tetrachloride[98–100] or puromycin[101], as has been suggested also by Robinson and Seakins[101].

Since the accumulation of triglyceride in the liver of the ethionine-treated animal is probably due to an interference with the synthesis of the protein moiety of some lipoproteins, it is possible that the altered lipid metabolism is only a special instance of a more general phenomenon in which the synthesis of several types of conjugated proteins by the liver is interfered with by the ethionine-induced inhibition of protein synthesis. On this basis, it might be expected that cellular components, other than triglyceride, representing prosthetic groups of conjugated proteins such as some complex lipids, polysaccharides, porphyrins, coenzymes, etc., may also show accumulations or other derangements as a consequence of the interference with the synthesis of their associated protein. The recent report of the accumulation of diastase-resistant periodic acid–Schiff-positive material, presumably polysaccharide, in the liver of ethionine-treated rats may indeed be an example of such a derangement[102].

Other Effects of Ethionine

It must be emphasized that the effects of adenine or ATP are specific in that these compounds prevent or reverse only some effects of ethionine. For example, the ethylation of transfer RNA by ethionine or the incorporation of the analogue into liver protein is not affected by adenine[103]. The inhibition by ethionine of methylation of transfer RNA from methionine or of transmethylation to lecithin precursors is not prevented by the administration of adenine or ATP, even though the inhibition of incorporation of methionine into liver protein is completely counteracted in the same animal[104] (Fig. 4). Analogous observations have also been made in respect to morphological changes in the liver induced by ethionine. Although adenine injections protect against fatty liver, other morphological changes are not prevented by this purine[78]. These results with adenine are in contrast to those with methionine, a compound which protects against almost all the inhibitory effects of ethionine (Fig. 4).

It is now evident that ethionine administration is rapidly followed by a striking drop in the hepatic ATP concentration and a concomitant accumulation of S-adenosylethionine and that each of these biochemical effects is, in turn, the initiator of several chemical and morphological consequences leading to characteristic manifestations of disease. Although the rapid induction of an ATP deficiency is one of the major effects of ethionine, as briefly reviewed in this report, there are other effects related to ethionine–methionine interaction (Fig. 4) which are also of potential importance in explaining the biochemical pathology of other acute and chronic changes induced by ethionine. In regard to these changes it should be emphasized that some effects observed when relatively large doses of ethionine are administered, such as the investigations reported here, do not appear to occur when much smaller amounts of ethionine are administered in the diet during the induction of liver cancer. Thus it is possible that phases of ethionine metabolism other than those concerned with ATP deficiency are related to its carcinogenic effect.

General Implications

An obvious by-product of this work is the availability of a technique to investigate several aspects of ATP metabolism under reasonably controlled conditions in an intact animal. Since the S-adenosylethionine molecule appears to be relatively stable metabolically in comparison with the ATP molecule, it is now possible to trap a considerable portion of the adenine of the cell through the reaction of ATP with ethionine and in this way measure approximate minimal rates of *de novo* synthesis of ATP from a variety of precursors. The preliminary results of such an investigation have already suggested that, in the ethionine-treated animal, the ATP molecule can be more readily made from adenine than from other precursors such as glycine, formate and glutamine, which are used in the more complex *de novo* synthesis[27].

It is noteworthy that the results of the work recorded here are consistent with the thesis that there exists a priority system or a compartment system in the intact cell for available ATP[105]. Some ATP-requiring systems such as nucleic acid synthesis, appear to be especially sensitive to a decrease in the ATP level while others, such as the synthesis of triglyceride from fatty acids and glycerophosphate, are not. Whether these differences are a reflexion only of the Km values of the reactions or are dependent also on the existence of intracellular compartments are questions which possibly may be approached with the aid of trapping systems such as that described here with ethionine. The investigations of ethionine

Note that adenine counteracts only those effects due to ATP deficiency while methionine counteracts all effects

also offer further support for the suggestion that protein synthesis in the rat liver[49,51,106–108] resembles more the system in some micro-organisms[65,109,110] and in some other mammalian cells[54–59,66–70,111–115] than in reticulocytes[52] in being dependent on a labile and short-lived messenger RNA.

An interesting facet of this work is the discovery of a 'cure' for an experimental disease, based on a knowledge of pathogenesis. The therapeutic use of adenine and related compounds in the ethionine-treated animal would not have been rational except on the basis of our present understanding of the mechanism of action of ethionine. The experience with this model system strengthens the conviction that a whole new system of therapeutics awaits the detailed knowledge of the biochemical-morphological alterations during the development of each disease process.

Finally, the investigation of some aspects of the biochemical pathology of hepatic ATP deficiency induced by ethionine has given new insight into several facets of cell metabolism and structure in relation to disease. The liver cell within a few hours after ethionine administration is a seriously altered cell with a level of ATP only about 20 per cent of the control and with a residuum of nucleic acid and protein synthesis of only 10–20 per cent. Despite the persistence of these abnormalities for at least 24 h, the liver cell does not die. It is therefore evident that the inhibition of protein synthesis, seen with several hepatotoxic necrotizing agents such as carbon tetrachloride[98–100] or dimethylnitrosamine[116], is not sufficient cause *per se* to induce cell death and necrosis. This strengthens the notion that the death of a cell, like many other reactions of the cell to environmental alterations of both physiological and pathological magnitude, is a highly selective process and that there may exist key metabolic reactions in a cell, the interference with which results in irreversible cell degeneration. A knowledge of such reactions might well help to lay a new foundation for the understanding and control of some diseases.

This work was supported in part by research grants from the Life Insurance Medical Research Fund, the American Cancer Society, the National Cancer Institute (*CA*–06074), the National Institute for Arthritis and Metabolic Diseases (*AM*–05590), (*AM*–06541), U.S. Public Health Service, and a training grant from the National Institute for General Medical Sciences (2*G*–135).

INITIATION OF POLYPEPTIDE CHAINS IN THE RETICULOCYTE CELL-FREE SYSTEM

By DR. JOHN O. BISHOP

Institute of Animal Genetics, Edinburgh

IN the course of protein synthesis in mammalian cell-free systems, ribosomal monomers are released from the polyribosomes[1-3]. At the same time some monomers become associated with the polyribosome fraction, possibly by attaching to one particular site on each polyribosome[2,4]. Release is more frequent than attachment, so that the net effect of incubation in the cell-free system is the degradation of the polyribosome fraction and the accumulation of ribosomal monomers[1-3]. It has been suggested that the attachment of a ribosomal monomer precedes the initiation of the polypeptide chain and similarly that the completion of the chain is followed by the release of the associated monomer[1,5,6]. Recent studies with HeLa cell and rabbit reticulocyte cell-free systems provide support for this interpretation[2-4].

In the *Escherichia coli* cell-free system polyphenylalanine is synthesized in response to the addition of polyuridylic acid (poly-U)[7]. It will be assumed here that in the reticulocyte cell-free system, too, poly-U-dependent phenylalanine incorporation[8] represents polyphenylalanine synthesis. In essential agreement with this assumption, the incorporated phenylalanine is not rendered soluble in trichloroacetic acid by either trypsin or chymotrypsin.

If the ribosomal monomers which are released from the polyribosome in the course of hæmoglobin synthesis are competent to initiate polypeptide chains, it may be predicted that they will initiate polyphenylalanine chains when poly-U is present. Indirect evidence[9,10] does indeed suggest that ribosomes which are attached to polysome complexes at the outset of incubation in the cell-free system may later become available for polyphenylalanine synthesis. The present studies constitute a more direct approach to this question.

It has been shown elsewhere[10] that rabbit reticulocyte polyribosome (*P*1) and ribosomal monomer (*P*2) fractions can be prepared by differential centrifugation. Fraction *P*1 is contaminated by ribosomal monomers to the extent of about 25 per cent and fraction *P*2 is similarly contaminated by polyribosomes. When titrated with poly-U, fraction *P*2 showed a single maximum of phenylalanine incorporation at about 20 μg poly-U per mg ribosome. Fraction *P*1 showed a slightly higher maximum, at 40 μg poly-U per mg, followed by a sharp minimum and finally by a second region of high phenylalanine incorporation. It was suggested[10] that the phenylalanine incorporation which occurred when the polyribosome fraction (*P*1) was incubated with 40 μg poly-U per mg was partly due to the continuing release of monomers from the polyribosome in the course of protein synthesis. In agreement with this interpretation, Hardesty *et al.*[4] have shown that the addition of poly-A to the reticulocyte cell-free system inhibits the inception of hæmoglobin polypeptide chains. In the experiments reported here, this question is examined further by comparing the capacities of fractions *P*1 and *P*2 to initiate polyphenylalanine and hæmoglobin polypeptide chains in the cell-free system.

Initiation of Polyphenylalanine Chains. It has recently been shown[11] that, in the presence of optimal amounts of poly-U, phenylalanine incorporation with fraction *P*2 occurs in artificial polyribosomes with sedimentation coefficients characteristic of ribosomal dimers and trimers. The artificial polyribosomes may be visualized in another way, by incubating fraction *P*2 with radioactive poly-U (Fig. 1). Before incubation the optical density and radioactivity profiles were similar: the poly-U was apparently non-specifically associated with the ribosomal fraction (Fig. 1*a*). After 5 min incubation a polyribosome peak emerged in the 100–240*S* region (Fig. 1*b*). At this time a considerable amount of poly-U was also associated with the ribosome monomer fraction. After incubation for 10 min the polyribosome peak was still evident but had subsided (Fig. 1*c*).

Calculation of the total amount of ^{14}C-poly-U recovered from the gradients suggested that the emergence of the polyribosome peak was due to the preferential degradation of poly-U not bound to ribosomes[14]. Degradation of poly-U is further illustrated in Table 1. Approximately 1·4 μg of poly-U was rendered TCA-insoluble in 10 min at 37° C by 1 mg of ribosome fraction *P*2. One mg of the enzyme fraction similarly degraded about 1 μg of poly-U. Degradation by ribosome and enzyme fractions was approximately additive. The level of poly-U used in the experiments of Fig. 1 was sub-optimal for phenylalanine incorporation. When greater amounts were used, the polyribosome peak failed to emerge, presumably because

Table 1. DEGRADATION OF ^{14}C-POLY-U IN THE CELL-FREE SYSTEM

Incubation conditions	c.p.m. TCA-insoluble	% degradation
No incubation	664	0
Complete system	404	39
Complete minus ribosomes	550	17
Complete minus enzyme	494	25

One mg of fraction *P*2 was incubated for 10 min at 37° with 5·75 μg ^{14}C-poly-U in a total volume of 0·4 ml. containing the additives described in the legend to Fig. 1. The mixtures were chilled and precipitated with 1 ml. of cold 10 per cent TCA, washed and counted.

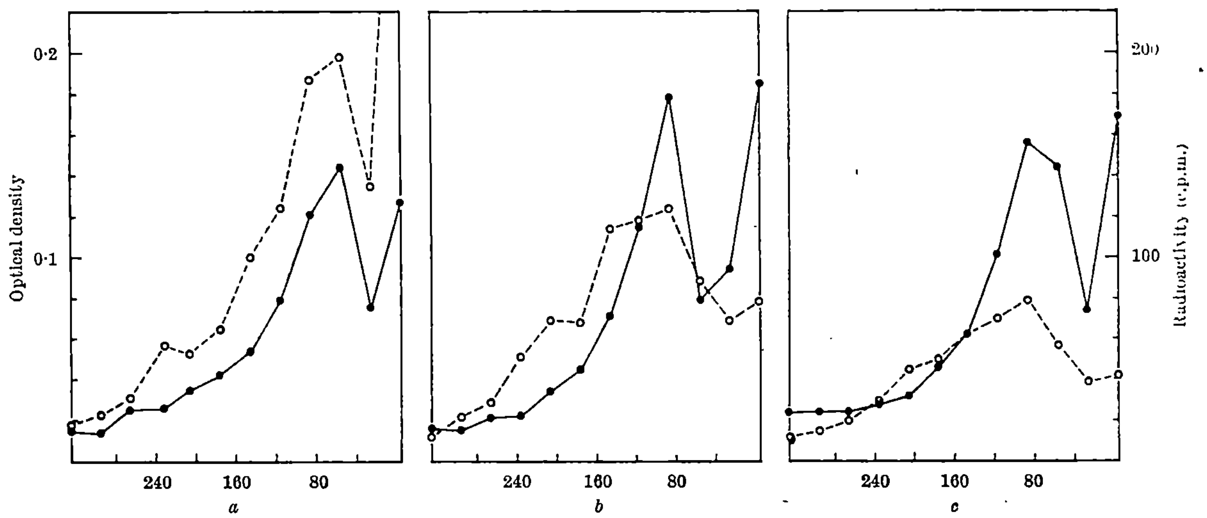

Fig. 1. Sedimentation analysis of the interaction between ribosome fraction *P*2 and ^{14}C-poly-U. (*a*) 10 min at 0° C; (*b*) after 5 min; (*c*) 10 min incubation at 37° C. Direction of sedimentation from right to left. Solid lines, optical density at 260 mμ; broken lines, radioactivity; abscissa, approximate sedimentation coefficients. 2 mg of fraction *P*2 was incubated with 11·5 μg poly-U (1,370 c.p.m.) in a total volume of 0·4 ml., containing in μmoles: ATP, 0·28; GTP, 0·08; creatine phosphate, 2·8; $MgCl_2$, 2; KCl, 16; *tris*-HCl, *p*H 7·2, 16; glutathione, 6; 18 *l*-amino-acids, 0·01 each; 5 μg creatine kinase, 30 μg yeast *s*RNA and 1 mg of enzyme fraction prepared by precipitating the ribosomal supernatant between 40 and 70 per cent ammonium sulphate saturation (refs. 10, 12). The mixtures were chilled, layered on a nearly linear sucrose gradient (5–20 per cent in 1·5 mM $MgCl_2$, 0·01 M KCl, 0·01 M *tris*, *p*H 8·1) and centrifuged for 1 h at 30,000 r.p.m. in the Spinco *SW* 39 rotor at 2° C. The bottoms of the tubes were pierced (ref. 13) and 20-drop fractions collected in the cold through a gauge 20 hypodermic needle. 0·05 ml. withdrawn from each fraction was diluted with 3 ml. water for the optical density measurements. 0·1 ml. of 1 per cent serum albumin was added to the remainder, and each was precipitated with 1 ml. of cold 10 per cent TCA for 30 min, collected on a 2 cm diameter Oxoid membrane filter, washed with 5 per cent TCA, dried with ethanol and ether and counted in a Packard 'Tricarb' liquid scintillation counter

the radioactivity not associated with the ribosomes was not degraded rapidly enough to reveal the transient polyribosome peak. These experiments suggest, however, that the extent of complex formation between poly-U and fraction *P*2 reaches a maximum within the first 5 min of incubation in the cell-free system.

Based on this finding, and the hypothesis that polyribosomes release free ribosomes to poly-U in the course of protein synthesis, predictions can be made regarding the time-course of the initiation of polyphenylalanine chains in the cell-free system. In the case of ribosomal monomers, all chains should be initiated during the first 5 min of incubation, and the remainder of the incubation period should be occupied by chain growth. Chain initiation would continue after the first 5 min only if ribosomes could complete one polyphenylalanine chain and initiate another in the course of the incubation. In the case of polyribosomes, on the other hand, the initiation of polyphenylalanine chains should continue so long as the completion of polypeptide chains and the release of free ribosomes from the polyribosome continues.

In view of the extensive cross-contamination of fractions *P*1 and *P*2, only quantitative predictions can be made about them. Fraction *P*2, rich in free ribosomes, should show the greater initial rise in polyphenylalanine chain inception, while fraction *P*1, rich in polyribosomes, should show the greater rate of chain inception after the initial period.

The rate of chain initiation was examined using a modification of the fluorodinitrobenzene technique. The total TCA-insoluble fraction of the incubation mixture was washed, treated with fluorodinitrobenzene, hydrolysed and extracted as previously described[15]. After drying, the ether extract was counted in a liquid scintillation counter with 10 ml. of a toluene-based counting fluid (0·5 per cent w/v PPO, 0·03 per cent w/v dimethyl POPOP in toluene). The acid phase was freed of ether and 1 ml. dried over potassium hydroxide and phosphorus pentoxide under reduced pressure. The residue was dissolved in 0·3 ml of water and counted with 15 ml of a dioxane counting fluid (8·6 g PPO, 70 mg dimethyl POPOP, 88 g naphthalene, 200 ml. xylene, 1 l. dioxane). Under these conditions quenching was negligible: the ether extracts counted with 55 per cent efficiency (^{14}C-benzoic acid standard) and the acid phases with 60 per cent efficiency. About 70 per cent of the radioactivity of the sample was recovered in the combined acid and ether extracts. In the case of polyphenylalanine synthesis with ^{14}C-phenylalanine, paper chromatography showed all the radioactivity of the acid phase to coincide with the position of free phenylalanine, indicating that acid hydrolysis was complete.

When either ribosome fraction was incubated with 30 μg poly-U per mg ribosome, the number of *N*-terminal phenylalanine residues rose abruptly within the first 5 min (Fig. 2*a*). Fraction *P*2 showed a slightly greater initial rise than fraction *P*1 (in similar experiments this difference has usually been greater). With both fractions the initiation of *N*-termini continued at a steadily decreasing rate during the remaining 35 min of incubation. Throughout this time the rate of chain initiation was about twice as great with fraction *P*1 as with *P*2. The levels of chain initiation by the two fractions after 5 min incubation are more similar than perhaps might have been expected. However, from the time-course of hæmoglobin synthesis in the cell-free system[12] and the linear relationship between incorporation and polyribosome breakdown[3], it may be concluded that the release of free ribosomes from the polyribosome is greatest in the early minutes of incubation. This would tend to equalize the extent of chain initiation by the two ribosome fractions, measured after 5 min. These results thus bear out the predictions made, and confirm that the polyribosome releases free ribosomes to poly-U in the course of incubation in the cell-free system.

Analyses of the time-course of total incorporation and of chain growth are consistent with the same interpretation. As previously shown[10], the rate of total incorporation with fraction *P*2 decayed during the 40-min incubation, while the rate of incorporation with fraction *P*1 was more nearly linear (Fig. 2*b*). In the early minutes of incubation fraction *P*2 incorporated phenylalanine twice as rapidly as fraction *P*1. The rate of growth of the polyphenylalanine chains is shown in Fig. 2*c*. From 5 to 40 min of incubation the average chain-length synthesized with fraction *P*2 increased from 65 to 222 residues. The comparable values for fraction *P*1 were 39 to 188 residues. The lesser chain-length throughout

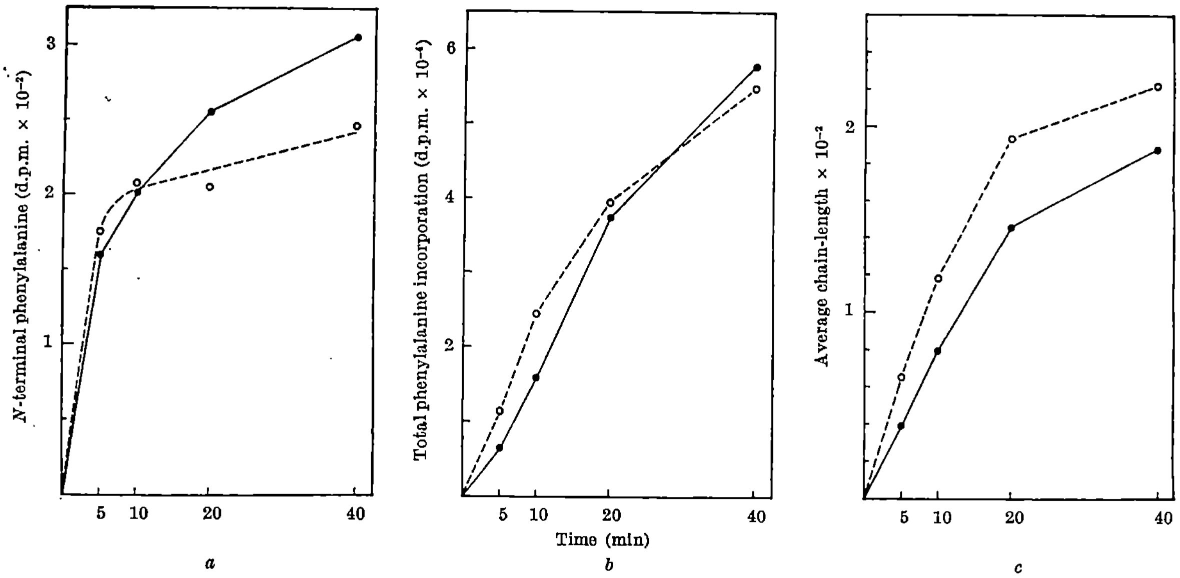

Fig. 2. Incorporation of ^{14}C-phenylalanine by ribosome fractions in the presence of poly-U. (*a*) *N*-Terminal phenylalanine; (*b*) total phenylalanine incorporated; (*c*) average chain-length of polyphenylalanine. Solid lines, fraction *P*1; broken lines, fraction *P*2. 1 mg of the appropriate ribosome fraction was incubated at 37° C in a total volume of 0·4 ml. containing the additives described in the legend to Fig. 1 except that 30 μg of unlabelled poly-U was added and 0·02 μmole ^{14}C-phenylalanine (22×10^6 d.p.m./μmole) was substituted for 0·01 μmole ^{12}C-phenylalanine. Following incubation the tubes were chilled, 10 mg hæmoglobin was added, and the mixtures were precipitated with TCA and analysed as described in the text

the incubation with fraction *P*1 may be attributed to the continuing initiation of polyphenylalanine chains by the free ribosomes released from the polyribosomes during cell-free incubation.

Assuming a coding ratio of three, an average polyphenylalanine chain-length of 220 residues corresponds to an average poly-U chain-length of 660 residues. This is in good agreement with the demonstration that the optimum chain-length for phenylalanine incorporation in a bacterial cell-free system is between 500 and 750 residues[16]. The poly-U used in the experiments described here was synthesized using *Micrococcus lysodeikticus* polynucleotide phosphorylase, partially purified to stage III of Singer and Guss[17] and heated for 5 min at 60° (ref. 18) before storage at –15° C. The polymer was isolated by extraction with phenol, passage through 'Sephadex *G*-25', ethanol precipitation and dialysis. Ultracentrifugation results are not available, but the average chain-length measured by the release of inorganic phosphate during digestion with alkaline phosphatase was of the order of 50 residues. Since the average polyphenylalanine chain-length was 5 times greater, the existence of a selective mechanism in the interaction between ribosome and poly-U is implied. To account for the 2·5 mμmoles phenylalanine incorporated, 7·5 mμmoles UMP would be required; that is, about 2¼ μg out of a total of 30 μg added. Selection is evidently not ruled out on a quantitative basis. Using a different method, Gilbert[19] has found an average chain-length of only 40 residues when *E. coli* ribosomes were incubated with unfractionated poly-U. This suggests that reticulocyte ribosomes may discriminate more efficiently against shorter polymers than *E. coli* ribosomes, and provides an explanation of the higher optimum poly-U level observed with reticulocyte ribosomes.

Initiation of Hæmoglobin Polypeptide Chains. Isolated reticulocyte polyribosomes contain incomplete polypeptide chains with an average chain-length approximately one-half that of complete hæmoglobin polypeptide chains[15]. In the cell-free system a proportion of these chains is completed and released to the soluble fraction, and at the same time free ribosomes are released from the polyribosome[3]. If all the completed polypeptide chains were released, and all the ribosomes made available in this way initiated fresh polypeptide chains, effective uniform labelling would be observed in the cell-free system. Analysis of the total TCA-precipitable fraction of the incubation mixture after labelling with ^{14}C-valine would show the same relationship between *N*-terminal and total radioactivity as found with authentic hæmoglobin; that is, 8·4 per cent of the valine incorporated would be in the *N*-terminal position[15]. Deviations from this value represent a failure either of the release of ribosomes from the polyribosome at the completion of chain synthesis, or of the inception of fresh polypeptide chains by the released ribosomes. The latter interpretation is strongly favoured by the demonstration[3] of a linear relationship between incorporation and polyribosome breakdown in the presence of poly-A.

In cell-free experiments with fraction *P*1, 1·4–2·2 per cent of ^{14}C-valine incorporation was *N*-terminal (Table 2). Thus only 16 to 25 per cent of the ribosomes which had completed polypeptide chains succeeded in initiating new ones. Since fraction *P*1 is contaminated by free ribosomes, the true proportions were probably smaller. This is illustrated by an experiment in which fractions *P*1 and *P*2 were compared (Table 2, experiment 3). The percentage of the total valine incorporation which was *N*-terminal was twice as great in the case of fraction *P*2, due presumably to the preponderance of free ribosomes in this fraction. Hardesty *et al.*[4] report the value of 3·4 per cent *N*-terminal valine in hæmoglobin synthesized in the cell-free system, showing that the probability of a free ribosome initiating a fresh polypeptide chain is greater under their conditions of incubation.

In parallel experiments with and without added poly-U we can compare the absolute amounts of *N*-terminal phenylalanine and *N*-terminal valine in polyphenylalanine and hæmoglobin respectively. Up to twice as

Table 2. CHAIN INITIATION IN THE CELL-FREE SYSTEM

Experiment	1	2	3
Fraction *P*1, *N*-terminal valine	9·4 (1·7%)	5·3 (2·2%)	14·2 (1·4%)
Fraction *P*2, *N*-terminal valine			13·6 (2·7%)
Fraction *P*1 + poly-U, *N*-terminal phenylalanine	11·8	13·9	15·2

3 mg of the ribosome fraction was incubated for 40 min at 37° C in 3 volumes of the incubation mixture described in the legend to Fig. 2. Either ^{14}C-valine alone, or ^{14}C-phenylalanine and 30 μg poly-U per mg ribosome, was added. *N*-terminal analysis was carried out as for Fig. 2. *N*-terminal incorporation is expressed as μμmoles of radioactive amino-acid per mg ribosome.

much phenylalanine as valine was found in the *N*-terminal position (Table 2). Thus the probability that a free ribosome will initiate a polyphenylalanine chain in the cell-free system is as much as twice its probability of initiating a hæmoglobin chain, that is, something less than 0·5.

A current model of protein synthesis suggests that a cycle of ribosomal events occurs during the synthesis of a polypeptide chain[1,3,6]. The initiation of chain synthesis is thought to follow the attachment of a ribosomal monomer to the informational RNA moiety of a polyribosome. As chain synthesis proceeds, the monomer is thought to travel along the strand of RNA, and when chain synthesis is complete, polypeptide and ribosome are thought to become detached from the informational RNA and thus from the polyribosome. Investigations with cell-free systems have shown a correlation between chain initiation and monomer attachment[4] and a similar correlation between chain completion and the release of monomers from the polyribosomes[2,3]. However, protein synthesis in cell-free systems is a limited reaction. Furthermore, incubation in the cell-free system produces a *net* degradation of the polyribosomes and an accumulation of free ribosomes[1–3]. This increase in the number of ribosomal monomers, however, was not accompanied by an increase in polyphenylalanine synthesis at the poly-U optimum[10]. Thus it may reasonably be asked whether the lesion in protein synthesis in the cell-free system might not be this very release of ribosomal monomers from the polyribosome.

Ribosomes are conserved during protein synthesis in living cells. Therefore if polyribosome breakdown occurs in the cell, the ribosomal monomers released must be capable of reattachment to the polyribosomes. An alternative possibility would be that free ribosomes are not released from polyribosomes or are only released as the capacity of the cell for protein synthesis is exhausted. However, the evidence presented here, and in a separate publication[10], indicates that a proportion of the monomers released from polyribosomes in the cell-free system is able to initiate polyphenylalanine chains in conjunction with poly-U. The possibility remains that these ribosomes are nevertheless deficient in a special function required for attachment to the endogenous informational RNA but not for attachment to poly-U. In the absence of any evidence for the existence of such a function, the present work supports the hypothesis that ribosomal monomers recurrently become detached from the polyribosome during protein synthesis.

FRACTIONATION OF TRYPSIN BY PAPER ELECTROPHORESIS

By A. IACHAN, G. B. DOMONT, L. V. DISITZER and J. C. PERRONE

Laboratory of Protein Chemistry, Instituto Nacional de Tecnologia, Rio de Janeiro, Brazil

PREVIOUS work from this laboratory[1–3] has demonstrated the heterogeneity of crystalline trypsin by paper and starch column electrophoresis. This article presents an electrophoretic method of greater resolution. Using this technique it was possible to demonstrate in a sample of crystalline trypsin the occurrence of fractions showing different ratios of proteolytic to amidasic activity.

In the experiments recorded here a buffer of pyridine acetate of *p*H 4·9 (0·48 : 0·56 : 98·96 v/v of acetic acid : pyridine : water) was used for electrophoresis in a Durrum-type apparatus. To a strip of Whatman 3 filter paper of 12 × 50 cm, 0·12 ml. of an 8 per cent trypsin solution in 0·001 N hydrochloric acid were applied. An electrical tension of 450 V was used and the experiment was allowed to run for 5 h in the cold room. In these conditions at the end of the experiment the temperature of the buffer was 9° C. The strip, while still wet, was cut in 1-cm wide transversal segments and transferred individually to test-tubes containing 3 ml. of a 0·25 M pyridine formate buffer of *p*H 2·7. This extraction was allowed to continue for about 20 h in the cold room. The extract of each tube was then analysed for protein content, proteolytic activity against azo casein and amidasic activity towards α-benzoyl-L-arginine amide (BAA).

The protein content was determined by the Folin–Lowry[4] method as applied to the 'auto analyser' system[5]. Proteolytic activity against azo casein was measured by the method of Charney and Tomarelli[6]. The hydrolysis of BAA was followed colorimetrically in the auto analyser[7]. Chromatography of trypsin in carboxy methyl cellulose was carried out according to the method of Liener[8].

The trypsin samples used in this work were purchased from the Worthington Biochemical Corporation ('Cryst. Trypsin, lyophilized, lot *TL* 747–58'), Freehold, New Jersey, and from Novo Industri ('Cryst. Trypsin Novo, batch 114–3'), Copenhagen, Denmark.

The results obtained by the fractionation of the Worthington trypsin are shown in Fig. 1. The presence of three distinct fractions is clearly shown, and all of them are active against azo casein. In the conditions of these experiments, however, the slower fraction (F_1) showed no activity towards BAA, while the faster fractions (F_2 and F_3) are active. The activity of each separated fraction is

Table 1

	Worthington trypsin				Novo trypsin			
	T*	F_1	F_2	F_3	T*	F_1	F_2	F_3
Proteolytic activity† (azo casein)	4·70	6·85	3·90	1·10	7·4	8·35	2·4	1·0
Amidasic activity‡ (α-benzoyl-L-arginine amide)	0·62	0·71	0·10	0·0	1·10	1·20	0·35	0·15
Ratio (proteolytic to amidasic)	7·8	9·5	39	—	6·7	6·9	6·8	6·7

* Unfractionated trypsin.

† The specific activity is given as the slope, multiplied by 10^3, of the straight line obtained by plotting the absorbance at 440 mμ against trypsin concentration in micrograms per millilitre.

‡ Same as above but plotting absorbance at 620 mμ.

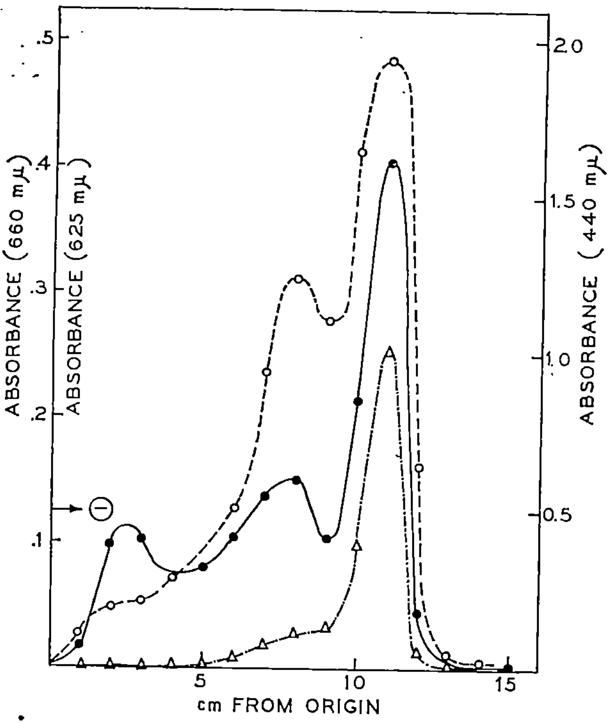

Fig. 1. Paper electrophoresis of a sample of Worthington trypsin. ●, Protein value (absorbance at 660 mμ); ○, proteolytic activity (absorbance at 440 mμ); △, amidasic activity (absorbance at 625 mμ)

given in Table 1 and shows that the specific activity of F_3 for both substrates is higher than that of the unfractionated enzyme.

The fact should be noted that the ratio obtained by dividing the proteolytic specific activity by the amidasic activity is different for each fraction. These results were observed only with the sample of Worthington trypsin.

These findings are consistent with those obtained by the electrophoretic fractionation of this same sample of trypsin in starch columns at *p*H 2·7 (ref. 3) which showed that the peaks representing the maximum of proteolytic activity and amidasic activity are not coincident.

The fractionation of Novo trypsin is presented in Fig. 2 and shows the appearance of only two fractions while the presence of a third slower fraction is only indicated. The specific activity of these three fractions is also given in Table 1 together with the calculated ratios of proteolytic activity to amidasic activity. These ratios for the sample of Novo trypsin examined are the same for all fractions obtained.

Electrophoresis of both samples of trypsin were also carried out in the presence of stabilizing concentrations of calcium. In this case calcium chloride was added to the *p*H 2·7 buffer to obtain a 0·05 M concentration of Ca^{++}. The trypsin samples were dissolved in this calcium-containing buffer and incubated for 2 h at 37° C before electrophoresis. The fractionation diagrams obtained by electrophoresis of the calcium-treated samples of trypsin were in all respects similar to those recorded in Figs. 1 and 2.

In order to test a possible degradation of trypsin during the electrophoretic run the main fraction (F_3) was extracted, freeze dried and again submitted to the same electrophoretic fractionation process. The results of this experiment are recorded in Fig. 3 and show the presence of only one fraction which was found to be active against both substrates.

A search for degradation products was carried out by treating with ninhydrin the paper strip after the electrophoretic run. This test was also negative and showed that no autolysis products reacting with ninhydrin were formed during electrophoresis.

These experiments tend to demonstrate that no degradation or formation of artefacts takes place during electrophoresis in the conditions employed in this investigation.

The appearance in the Worthington trypsin of fractions giving different ratios of proteolytic to amidasic activity could be explained by gross contamination of this sample with some other proteolytic enzyme such as chymotrypsin. However, the possibility of contamination with chymo-

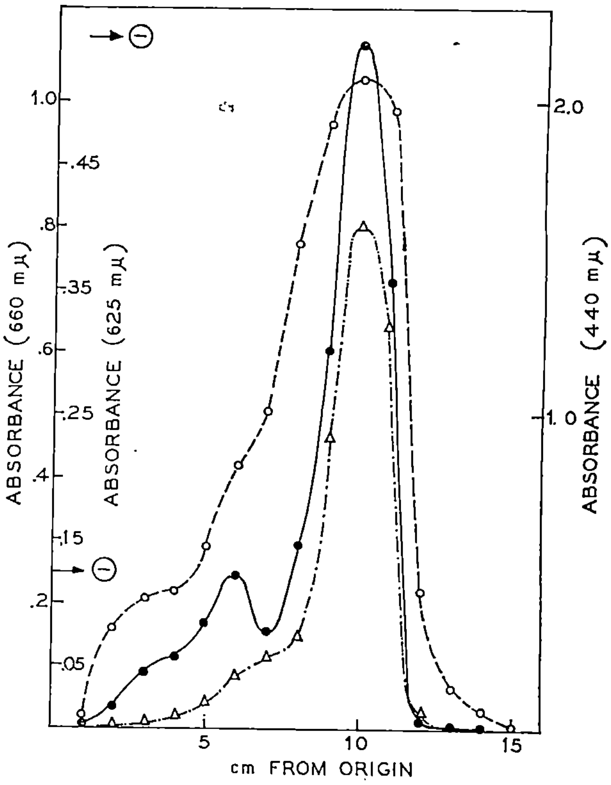

Fig. 2. Paper electrophoresis of a sample of Novo trypsin. ●, Protein value (absorbance at 660 mμ); ○, proteolytic activity (absorbance at 440 mμ); △, amidasic activity (absorbance at 625 mμ)

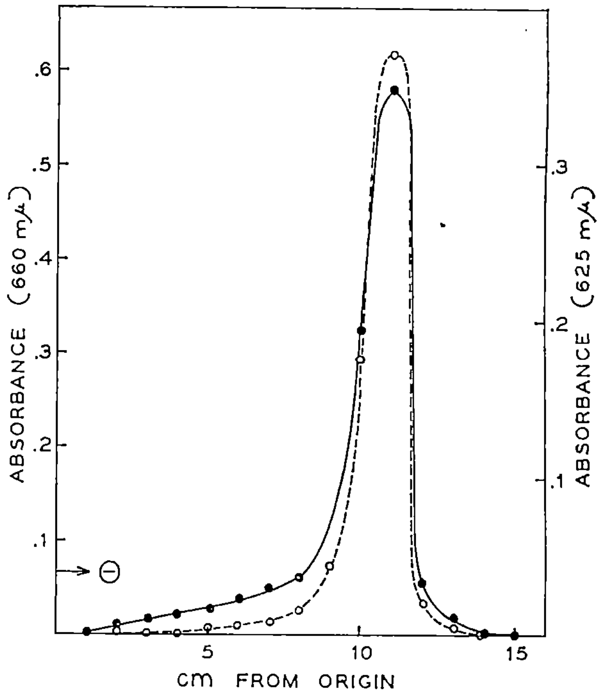

Fig. 3. Re-electrophoresis of the main fraction from the sample of Worthington trypsin. ●, Protein value (absorbance at 660 mμ); ○, amidasic activity (absorbance at 625 mμ)

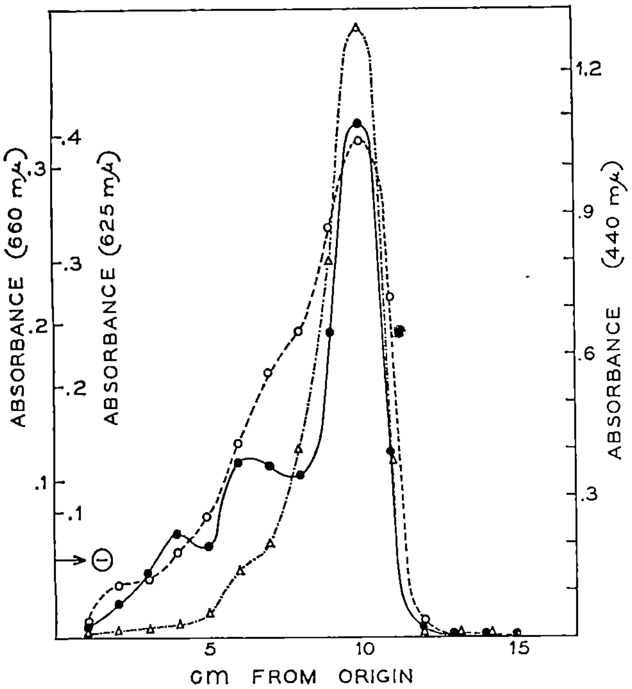

Fig. 4. Paper electrophoresis of the main trypsin fraction obtained by chromatography in carboxymethylcellulose. ●, Protein value (absorbance at 660 mμ); ○, proteolytic activity (absorbance at 440 mμ); △, amidasic activity (absorbance at 625 mμ)

trypsin was ruled out by paper electrophoresis at *p*H 2·7 (ref. 1). At this *p*H, chymotrypsin remains at the application point while trypsin migrates towards the anode, and when the Worthington trypsin was analysed by this method no proteolytic activity was found at the origin.

In order to correlate the results obtained with the present method of fractionation with those of Liener[8] using chromatography in carboxymethyl cellulose (CMC) the main fraction obtained from the Novo trypsin by this method was investigated by paper electrophoresis at *p*H 4·9. Prior to electrophoresis the main chromatographic fraction was dialysed in the cold against *p*H 2·7 pyridine formate buffer and freeze dried. The data obtained from this fractionation are recorded in Fig. 4 and show that the main fraction resulting from the chromatography of trypsin in CMC is heterogeneous when analysed by paper electrophoresis at *p*H 4·9. The fractionation diagram presented in Fig. 4 is similar to those obtained in the same conditions with the unfractionated enzyme.

The presence in crystalline trypsin of fractions each one showing a different ratio of proteolytic activity to amidasic activity was unexpected. One possible explanation for the observation would be the occurrence of limited autolysis of the enzyme during isolation. Changes in the specificity of trypsin following autolysis were observed by Bresler *et al.*[10]. Hakim *et al.*[11] have also obtained experimental evidence indicating that changes can occur in the specificity of trypsin following limited autolysis of this enzyme. The work of Viswanatha and Liener[12] is also pertinent to this question in showing that the specificity of the active fragment resulting from the peptic activation of acetyl trypsinogen was different from that of trypsin.

We have suggested in a previous article[3], based on the observations of Liener[8] and Gladner and Folk[9], that limited autolysis of trypsin resulting in the cleavage of lysine bonds near the trypsin C-terminal residue could account for the occurrence of the observed heterogeneity.

FRACTIONATION OF RIBONUCLEIC ACIDS

By Dr. R. BARBER and Dr. A. S. JONES
Department of Chemistry, University of Birmingham

THE fractionation of ribonucleic acids (RNA) on a new type of exchanger in which guanine residues were linked to cellulose has been previously reported[1]. The results indicated that the RNA was attached to the exchanger by means of hydrogen bonds. Other workers have since described similar systems[2]. This work has now been extended to the study of an exchanger in which a derivative of uracil was attached to cellulose. This was made by treating partially acetylated cellulose with 5-hydroxymethyluracil[3] in the presence of dilute acid, and then removing the acetyl groups by mild alkaline hydrolysis. The procedure was as follows:

Cellulose acetate (British Celanese, Ltd.; 2·4 acetyl groups per glucose unit; 125 g) was allowed to stand in 7·5 per cent nitric acid (1 l.) at room temperature for 19 h with occasional stirring. The product was filtered off, washed with water until free from acid and dried in the air at 90°–100°. It contained 1·8 acetyl groups per glucose unit. This partially acetylated cellulose (13 g) and 5-hydroxymethyluracil (8 g) were suspended in dimethylformamide (80 ml.) containing 2 per cent (w/v) of dry hydrogen chloride. The mixture was shaken at room temperature until complete solution was obtained and then this was allowed to stand at 50° for 40 h. The solution was cooled, poured into sodium bicarbonate solution (200 ml.) and the resulting precipitate filtered off, and washed alternately with hot water and hot ethanol until the washings contained no material absorbing in the region 230–300 mμ. The product at this stage contained one 5-hydroxymethyluracil (HMU) residue per 5 glucose units (determined by hydrolysis with boiling N hydrochloric acid and determination of the 5-hydroxymethyluracil spectrophotometrically). The material was suspended in acetone (200 ml.) and water (about 10 ml.) added until a homogeneous solution was obtained and then 2 N sodium hydroxide (50 ml.) added. This hydrolysed off the acetyl groups. The resulting gelatinous precipitate was washed with 0·5 M sodium chloride and stored in suspension. The yield was 40 per cent, and the product contained one 5-hydroxymethyluracil residue per

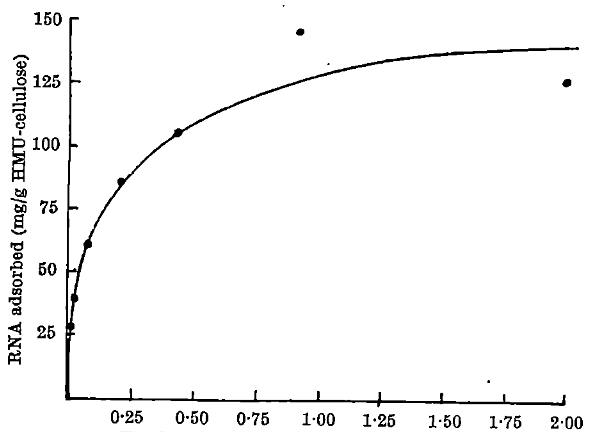

Fig. 1. Adsorption of yeast *m*RNA on HMU-cellulose (1 mg/ml. of RNA soln.) at 0° in 0·5 M NaCl. Solution allowed to equilibrate for 18 h

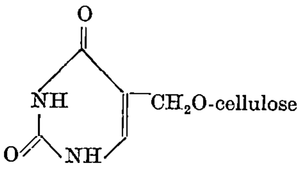
9 glucose units. It appeared that the more highly substituted molecules were soluble in water and were removed by the washing procedure. Several batches of this exchanger were prepared, and the procedure was found to be reproducible.

The exchanger (HMU-cellulose; I) adsorbed yeast microsomal RNA (*m*RNA)[4] from solution in 0·5 M sodium chloride and the amount adsorbed depended on the concentration of the RNA (Fig. 1). Material which still contained the acetyl groups did not adsorb the *m*RNA, neither did nylon nor polyacrylamide gel. The RNA could be eluted from the exchanger by lowering the ionic strength and/or increasing the temperature.



Attempts were made to fractionate yeast *m*RNA by the use of HMU-cellulose at 0° by elution with a gradient of decreasing salt concentration, but the time taken to reach equilibrium at this temperature was too long.

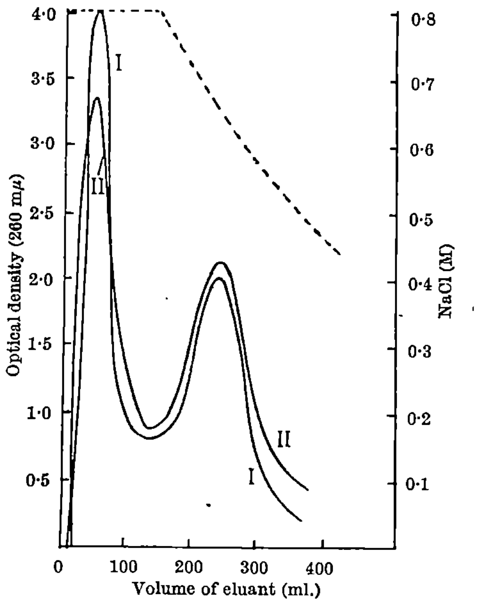


Fig. 2. Fractionation of *m*RNA on HMU-cellulose at 26°. The *m*RNA (30 mg) in 0·8 M NaCl was adsorbed on the column (18 cm × 1·8 cm diam.). Eluted at 7·5 ml./h 10 ml. fractions collected. I = yeast *m*RNA; II = pig liver *m*RNA (separate fractionations); ------, salt gradient

Fractionations of yeast *m*RNA and pig liver *m*RNA were carried out at 26°, but there was no appreciable difference between the nucleic acids from the two sources (Fig. 2). When the fractionation was carried out at 16°, however, there was a considerable difference (Fig. 3). The fractionations were also carried out by elution at constant ionic strength (0·35 M sodium chloride); small differences were found (Fig. 4), but it did not appear to be possible to separate the two ribonucleic acids from each other. The amount of RNA retained was apparently dependent on the amount of salt passed down the column as well as on the concentration. The ribonucleic acids were fractionated by this process into a strongly retained and a weakly retained fraction. This was a true fractionation as shown by the fact that the same proportion of the RNA was retained when different amounts of yeast *m*RNA were

For each fractionation, 25 mg of *m*RNA was adsorbed on a column of HMU-cellulose (18 cm × 1·8 cm diam.) and eluted with 0·35 M NaCl at 10°–11° (except second fractionation of *S. marcescens* *m*RNA when temp. was 16°). Flow rate 7·5 ml./h.

* F_1 = the first 37 per cent of the RNA eluted; F_2 = remainder of the RNA (eluted with water). Each column indicates an independent fractionation. For the base analysis one hydrolysis was carried out on each fraction and three chromatograms run for each hydrolysis.

fractionated on the same column and that when one tube of a fractionation was removed and refractionated it was far more homogeneous than the original *m*RNA (Fig. 5).

Samples of *m*RNA from yeast, pig liver and *Serratia marcescens* were fractionated on HMU-cellulose into a fraction eluted with 0·35 M sodium chloride and a fraction retained by 0·35 M sodium chloride but eluted by water. The temperature was kept constant (± 1°) by means of tap water; but there was a variation in the actual temperature (10°–16°) according to the time of year. The fractions so obtained were analysed for purines and pyrimidimes by hydrolysis with N hydrochloric acid, and separation of the nucleotides and bases by paper chromatography[5].

Table 2. STATISTICAL ANALYSIS OF THE RESULTS SHOWN IN TABLE 1

Significance of the differences in base content of the 1st and 2nd fractions.

(*a*) Yeast *m*RNA
  (1) Student's *t* test.
    Adenine, $t = 24{\cdot}3$ (2 deg. freedom) $P < 0{\cdot}002$.
    Uracil $t = 3{\cdot}83$ (2 deg. freedom), $P < 0{\cdot}1$.
  (2) Variance ratio test.
    Adenine, $F = 24{\cdot}0$ (5 and 12 deg. freedom) $P < 0{\cdot}001$.
    Uracil $F = 7{\cdot}4$ (5 and 12 deg. freedom) $P < 0{\cdot}05$.
No significant difference for guanine and cytosine contents.

(*b*) *S. marcescens* *m*RNA. Variance ratio test.
  (1) 1st fractionation (at 11°).
    Adenine $F = 81{\cdot}6$ (1 and 4 deg. freedom) $P < 0{\cdot}001$.
  (2) 2nd fractionation (at 16°).
    Adenine, $F = 87{\cdot}2$ (1 and 4 deg. freedom) $P < 0{\cdot}001$.
No significant difference for guanine, cytosine or uracil contents.

(*c*) Pig liver *m*RNA. No significant differences.

The results (Table 1) showed that in the case of yeast and *Serratia marcescens* *m*RNA there was a difference in the adenine contents of the first and second fractions (for statistical analysis see Table 2) but not in the case of pig liver *m*RNA. As was expected, with a column consisting of uracil residues the fractions containing the higher amount of adenine were the more strongly retained, indicating that the uracil residues were interacting with the adenine residues in the RNA. In support of this it was found that polyadenylic acid was retained strongly by HMU-cellulose and that polyuridylic acid was only weakly retained (Fig. 6). On this basis, however, it would have been expected that pig liver *m*RNA would have been retained less strongly than yeast *m*RNA when actually the opposite was the case. It appeared that the secondary structure of the *m*RNA was of importance, because if the *m*RNA was heated to 100° and slowly cooled before fractionation there was a change in the elution pattern; the pig liver *m*RNA was more strongly retained and the yeast *m*RNA less strongly retained by the HMU-cellulose. In the case of the yeast *m*RNA also no significant difference in the composition of the fractions could be detected; this showed that the fractionation depended on the method of isolation and storage of the *m*RNA.

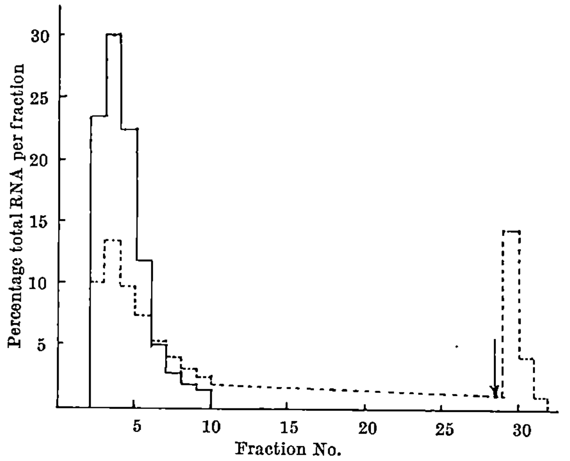

Fig. 5. Refractionation of yeast *m*RNA 25 mg of *m*RNA adsorbed on HMU-cellulose column (18 cm × 1·8 cm diam.) and eluted at 16° with 0·35 M NaCl and then with water (arrow shows start of elution with water). 10 ml. fractions collected. Flow rate 7·5 ml./h. Fraction 4 isolated and refractionated under the same conditions. - - -, original *m*RNA; ——, refractionation of fraction 4

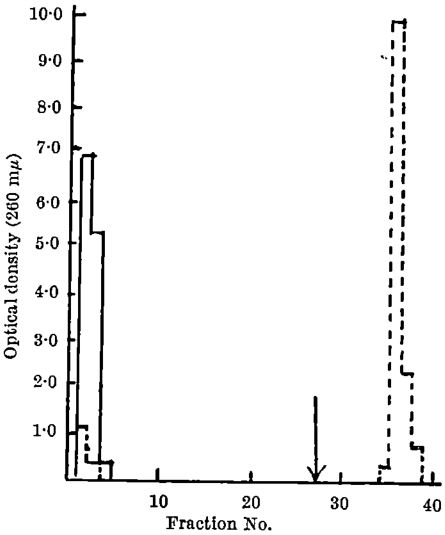

Fig. 6. Adsorption of polyribonucleotides on HMU-cellulose. - - -, polyadenylic acid (11 mg) adsorbed on the column (18 cm × 1·8 cm diam.) and eluted with 0·35 M NaCl and then with water (arrow shows start of elution with water). ——, polyuridylic acid (5 mg) adsorbed as above and eluted with 0·35 M NaCl. Temp. 13° in both cases. 10-ml. fractions collected. Flow rate 7·5 ml./h

Fractionations were also carried out on commercial yeast RNA under the same conditions except that M sodium chloride was used for the elution. In this case it appeared that the preparation would be more heterogeneous and that secondary structure would be of less importance. The results (Table 3) show that there were large differences in the composition of the fractions

Table 3. FRACTIONATION OF COMMERCIAL YEAST RNA ON HMU-CELLULOSE

	Moles of base/100 nucleotides			
	Original RNA	F_1	F_2	F_3
Guanine	27·18 ± 0·45	24·19 ± 0·24	26·84 ± 0·76	28·43 ± 0·37
Adenine	26·20 ± 1·85	21·10 ± 0·96	29·28 ± 0·44	30·56 ± 0·30
Cytosine	20·16 ± 0·46	22·85 ± 1·41	19·48 ± 0·13	18·82 ± 0·60
Uracil	26·24 ± 1·53	31·85 ± 1·24	24·39 ± 0·07	22·20 ± 0·67

Conditions for the fractionation were the same as described in Table 1 except that M sodium chloride was used for the elution. The commercial yeast RNA was supplied by Boehringer and Soehne, Mannheim.

F_1 = first 5 per cent of the RNA eluted: F_3 = last 5 per cent eluted (eluted with water); F_2 = 18 per cent of the total RNA eluted (eluted with M NaCl) before the last 5 per cent. The fractionation pattern was similar to Fig. 4 except that 95 per cent of the material was eluted with the M sodium chloride.

obtained, so that it can be concluded that polyribonucleotides can be fractionated on HMU-cellulose. In this case the adenine-rich fractions were retained as expected.

We thank Prof. M. Stacey for his advice and the British Empire Cancer Campaign (Birmingham Branch) for financial support.

SELECTIVE EXTRACTION OF A PROTEIN FRACTION FROM WOOL KERATIN

By R. A. DEDEURWAERDER, M. G. DOBB and B. J. SWEETMAN

Division of Protein Chemistry, C.S.I.R.O. Wool Research Laboratories, Parkville, Melbourne

THE reaction of tetrakis (hydroxymethyl) phosphonium chloride (THPC) with keratin has recently been examined by several authors[1-4]. We have now extended the scope of the previous work and have also investigated the reactions of a number of other organophosphorus compounds with the disulphide bonds of wool keratin. Since it has been shown previously that reduction in a solvent system which swells the wool fibre and thus promotes the diffusion of a reagent offers a method for the almost complete removal of disulphide bonds, we have investigated the reaction of several organophosphorus reducing agents in anhydrous formamide.

Samples of conditioned wool top (20° C, 65 per cent relative humidity) were treated for 24 h at 20° C and a 50/1 liquor/wool ratio with solutions or suspensions containing 5 per cent w/w (large excess) of either THPC, *tris* (diethylaminomethyl) phosphine (DEAMP), triethylphosphite (TEP), triphenylphosphine or tetraphenylphosphonium chloride in anhydrous formamide. The percentage disulphide reduction of each sample was estimated amperometrically[6] and found to be 70, 98–99, 97–98, 64–66 and 17–20 per cent respectively. The reductions with DEAMP and TEP were afterwards examined in greater detail.

The most interesting feature of this work is that we have been able to extract preferentially a protein located between the cuticular cells of the wool fibre. This protein has a distinctive amino-acid composition, and a brief description of its isolation and properties are of interest. After reduction of the wool with DEAMP in formamide, the liquor containing the extract was diluted with water and the solution afterwards treated with potassium iodoacetate at *p*H 8 to prevent the re-oxidation of sulphydryl groups. The extract, after dialysis against distilled water and freeze-drying, gave a protein residue amounting to 2–3 per cent of the initial weight of wool. The S-carboxymethyl protein was only completely soluble in aqueous solution above *p*H 10.

Amino-acid analysis of the hydrolysate shows the protein to be unusual in containing abnormally high percentages of glycine (27 per cent)*, tyrosine (11 per cent), phenylalanine (6·7 per cent) and tryptophan (1·7 per cent) and a low content of S-carboxymethyl cysteine. It is apparent from electron microscopic studies of the reduced fibre that this protein is located in the membrane complex between the cuticular cells of the wool fibre (Fig. 1). In fact, there is a tendency for these cells to be released from the fibre as is evident in Fig. 1. Furthermore, the method offers possibilities worth exploring for the isolation of cuticular cells for subsequent analysis. From the structural point of view the extraction appears to be selective and quite reproducible while the microfibrillar texture remains intact (Fig. 2). However, even after complete reduction, the extraction is incomplete, for in a few regions the membrane system is not completely removed.

A very heterogeneous protein fraction of similar composition[7] has also been isolated from wool by total extraction with urea-2-mercaptoethanol and fractionation by DEAE-chromatography. Moreover, Gillespie and Harrap[8,9] obtained a protein fraction which had a high tyrosine and glycine content and was insoluble in aqueous

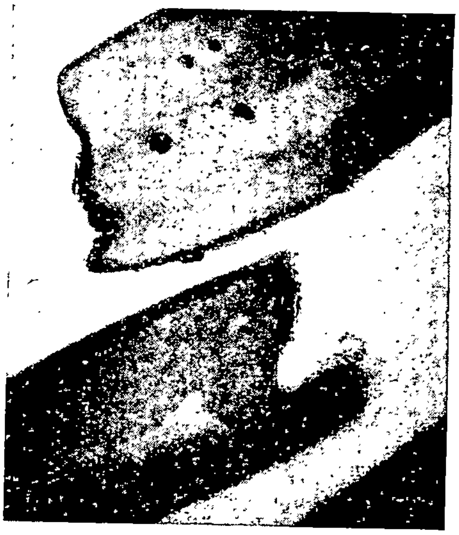

Fig. 1. Transverse section of merino wool cuticle treated with DEAMP in formamide and subsequently stained in silver nitrate (× 48,000)

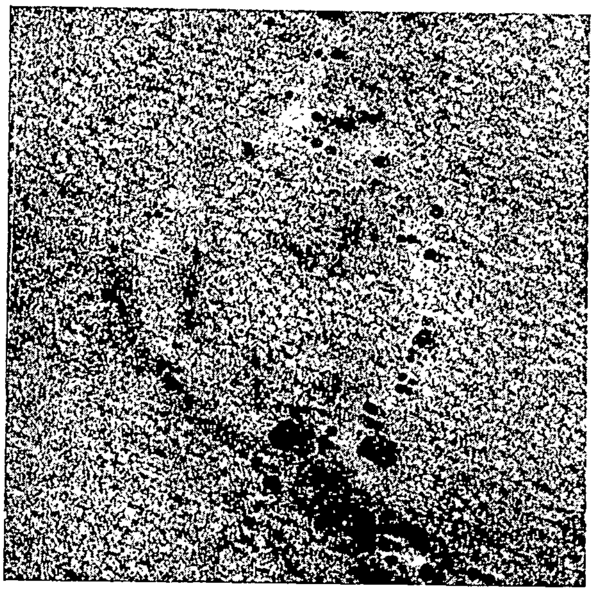

Fig. 2. Transverse section of merino wool treated as in Fig. 1 (× 200,000)

solution except at high pH values. It is therefore tempting to suggest that these proteins all have a common origin within the wool fibre.

---

* Percentages are based on the total nitrogen content of the protein hydrolysate.

It has been suggested[10] that tryptophan and tyrosine degradation may be responsible for the yellowing of wool under the action of sunlight. Our treatment, which removes a protein fraction containing a relatively high amount of these amino-acids, may therefore reduce the yellowing of wool by sunlight.

We have also investigated the reduction of disulphide bonds in wool with 0·3 M aqueous solutions of THPC and DEAMP at 40° in the range pH 1–9. Contrary to the results published by Jenkins and Wolfram[2] it was found that the rate of reduction increases with pH up to pH 5 and thereafter remains approximately constant. Using the foregoing conditions (pH 3–5), virtually quantitative reduction can be achieved in approximately 4 h. The trialkyl phosphines thus appear to be the most effective reducing agents so far described for reduction of disulphide groups in acid media.

It had previously been assumed[3] that reduction by aqueous THPC was associated with the absorption of the phosphonium ion on the fibre. However, we have been unable to detect any phosphorus above a level of about 0·02 per cent in samples reduced either in aqueous[2] or formamide media.

Reduction of model disulphides with tertiary phosphines can give rise to either thiol[11,12] or lanthionine-type[13] derivatives, depending on whether reductions are carried out in aqueous or non-aqueous media respectively. Under our experimental conditions we have found that DEAMP or TEP reductions of wool in formamide solution of disulphides in wool produce 30–64 μM lanthionine/g wool, while reduction in aqueous solution at pH 1–8 gives almost no lanthionine. However, Zahn and Vassiliadis[1] have observed lanthionine formation in aqueous media and at higher temperatures. We thank Mr. L. M. Dowling for determinations of lanthionine.

CRYPTORCHISM IN AUSTRALIAN MERINO SHEEP

By C. H. S. DOLLING and M. G. BROOKER

National Field Station, Gilruth Plains, C.S.I.R.O., Cunnamulla, Queensland, Australia

DURING an investigation of the inheritance of cryptorchism in medium wool Australian merinos, rams with only one or neither testicle descended into the scrotum, or with descended testicles of unequal size, were observed in several flocks.

Several workers have quoted the incidence of bilateral and unilateral cryptorchids in sheep. Glembockii and Moiseev[1] reported that approximately 8 per cent of cryptorchid lambs observed in the Valahian and the Précoce merino were unilateral, the left testicle being descended in each case. The number of unilateral cryptorchids was 14; it is likely that these were included in a total of 23 reported later[2], in 18 of which the left testicle had descended. Kochetkova[3] reported that approximately 10 per cent of the cryptorchids in another Précoce flock were unilateral, but did not record which testicle had descended. Wendt, Pohl and Mrosk[4] reported that most cases of cryptorchism which they observed in the mutton merino were bilateral.

The definition of cryptorchism used here is that of Sisson and Grossman[5], that is, retention of one or both testicles in the abdominal cavity or inguinal canal. In the 6 unilateral and 2 bilateral cryptorchids which have been slaughtered the missing testicles have been located in the abdominal cavity. Other animals have been scored by palpation of the scrotum, and any testicle not descended has been assumed retained in the abdominal cavity.

Cryptorchid rams have been inspected in medium wool flocks at Cunnamulla, Queensland, and in the New England district of New South Wales. These rams came from both horned and polled flocks (Table 1, *a*, *b* and *c*). Each polled ram would have been either homozygous or heterozygous for the dominant gene for polledness[6]. The numbers quoted cannot be used to estimate the relative frequencies of abnormal rams among those of the two horn types, because a random sample of flocks was not taken.

In the Cunnamulla flocks, 41 cryptorchids (85 per cent of the total) were unilateral, and in 40 of these the left testicle had descended. The ratio 40 : 1 differs significantly ($P < 0{\cdot}0001$) (ref. 7) from the 1 : 1 ratio expected if the side of descent were determined at random.

Table 1. NUMBERS OF MEDIUM WOOL MERINO RAMS OBSERVED WITH TESTICULAR ABNORMALITIES

Abnormality	No. of rams					
	Cunnamulla, Queensland			New England, N.S.W.*		
	Horned	Polled	Total	Horned	Polled	Total
No testicle in scrotum						
(*a*) Neither testicle descended to scrotum or palpable	1	7	8	0	20	20
One testicle in scrotum						
(*b*) Left testicle descended to scrotum, right testicle not palpable	8	32	40	0	3	3
(*c*) Right testicle descended to scrotum, left testicle not palpable	0	1	1	0	3	3
(*b*) or (*c*) One testicle descended to scrotum, other testicle not palpable	—	—	—	2	7	9
Two testicles in scrotum						
(*d*) Left testicle larger than right	8	2	10	N.R.†	N.R.	N.R.
(*e*) Right testicle larger than left	10	2	12	N.R.	N.R.	N.R.

* In the New England flock, groups (*b*) and (*c*) were scored as one group except at one lambing.

† N.R., not recorded, but may have been present.

Table 2. Location of Testicles in Normal Male Merino Fœtuses

Interval, service to slaughter (days)	Male fœtuses						
	No. observed	Testicles		Right kidney		Right testicle	
		Internal to inguinal ring	External to inguinal ring	Anterior* to left	Level with left	Anterior§ to left	Level with left
50	2††	2	0	0	0	0	0
60	3††	3	0	1	0	0	1
70	2†	2	0	1	0	1	0
75	1	1	0	1	0	1	0
80	2	0	2	2	0	—	—
85	5	0	5	5	0	—	—
90	2	0	2	2	0	—	—
100	3	0	3	3	0	—	—
105	4	0	4	4	0	—	—

* Right kidney is not completely anterior to left, but anterior surface of right kidney is anterior to anterior surface of left kidney.

§ Right testicle is not completely anterior to left, but anterior surface of right testicle is anterior to anterior surface of left testicle.

No observations were made on the symmetry of kidneys or testicles of unfrozen fœtuses or of those twisted slightly during freezing. The number of daggers indicates the number of such fœtuses in a group.

In the New England flock, 15 cryptorchids (43 per cent of the total) were unilateral. The 6 unilateral cryptorchids of one lambing only were examined in detail. In 3 lambs the left testicle had descended, in 3 the right.

To determine the fœtal age at which testicles migrate from the abdominal cavity to the scrotum in normal merinos, ewes bearing fœtuses of known ages were slaughtered. Each ewe had been removed from the mating pen 24 h after her first service was recorded. To prevent movement of organs during dissection, most fœtuses were frozen on removal and dissected while thawing.

Details of the observations are given in Table 2, the indication being that testicles pass through the inguinal ring between 75 and 80 days after conception.

Only one case has been reported in which a testicle might have descended after birth. In the flock of a co-operating breeder, a polled ram recorded by him as a bilateral cryptorchid at several weeks of age was observed with the left testicle descended at 1·5 years. No case has been observed of the withdrawal of a testicle after birth. Unless withdrawal takes place *in utero* between 80 days and full term, cryptorchism in merino rams probably results from the failure of one or both testicles to descend at 75–80 days of fœtal age.

The reproductive organs of vertebrates develop in association with the kidneys and their ducts[8]. In 8 adult merino rams slaughtered, the right kidney has been completely anterior to the left in each case; this is in general agreement with the situation described by Sisson and Grossman for adult sheep. An asymmetry was observed also in the kidneys of 19 male merino fœtuses (Table 2).

In the 3 of these which were aged 75 days or younger, the relative positions of the testicles were observed. In the youngest the two testicles were level, but in the other 2 the right was partly anterior to the left.

Asymmetry of testicles in the fœtus could be associated with the tendency of the left testicle to descend in unilateral cryptorchids in the Cunnamulla flocks. The left testicle probably begins to migrate before the right. The resulting asymmetry prior to actual descent to the scrotum would give the right testicle farther to travel during descent. As a consequence it may meet a mechanical or physiological block, such as the occlusion of the inguinal canal or a hormonal interference, which the left testicle evades. Retention of both testicles could be due to such a block acting on both sides, or to some other cause.

Among rams in which both testicles have descended but which are different in size, there is no indication that one is consistently larger than the other (Table 1, *d* and *e*). Factors producing asymmetry in testicle size thus seem to differ from those producing cryptorchism in Cunnamulla flocks.

As the investigation of the inheritance of cryptorchism progresses, it is hoped to investigate the migration of testicles in male fœtuses which have a known probability of developing into cryptorchids.

IMMUNOLOGICAL CONTROL OF FERTILITY IN FEMALE MICE

By Dr. R. G. EDWARDS

Physiological Laboratory, University of Cambridge

THE advantages and possibilities of an immunological method for the control of fertility have been discussed repeatedly[1]. The recent publication by Dr. Anne McLaren[2] on the immunological control of fertility in mice prompts the present communication of my results in this field and on the same species. I have examined fertilization in female mice immunized with homologous spermatozoa. Various schedules of immunization have been used, from a few subcutaneous or intraperitoneal injections of spermatozoa to two successive immunizations with spermatozoa emulsified in complete Freund's adjuvant followed by many subsequent immunizations with spermatozoa. The major intention has been to find out whether prolonging the immunization course causes progressive decline in fertilization rates.

For immunization, spermatozoa were stripped from the vas deferens of outbred adult mice, and between 10 and 50 × 10^6 fresh unwashed spermatozoa were injected at each immunization into outbred female mice. Three schedules of immunization were carried out. (1) Nine mice were given 3–5 subcutaneous and intraperitoneal injections of spermatozoa in saline at weekly intervals. (2) Twenty-one mice were given an initial subcutaneous injection of spermatozoa in Freund's adjuvant, followed by 2–5 subcutaneous and intraperitoneal injections of spermatozoa in saline at weekly intervals. (3) Twenty-one mice were given two courses of spermatozoa in Freund's adjuvant at an interval of two weeks, and after a further two weeks were injected intraperitoneally with spermatozoa in saline every four or five days. These mice received 3–11 subsequent intraperitoneal injections of spermatozoa, excluding the two initial injections with adjuvant. In groups 2 and 3, the adjuvant/spermatozoa emulsion was injected into four separate sites on the back at each immunization. Control mice were given identical courses of treatment, but substituting saline for sperm suspensions.

Between 6 and 36 days after the end of the immunization schedule, the female mice were paired with males of proved ability, and examined next morning for mating (judged by the presence of a vaginal plug). Immunization did not affect mating performance, the proportion mating on the first night of pairing being similar in the immunized and control groups. Females which mated were killed by ether between 12 noon and 5 p.m. on the same day, bled from the heart and the uterus and Fallopian tubes removed. The uterine contents were examined, special attention being given to any spermatozoa therein. Living eggs liberated from the ampulla of the Fallopian tubes were examined for evidence of fertilization under a phase-contrast microscope[3]. In all mice except six, the eggs could be classified as fertilized or unfertilized without difficulty. In the remaining six (two immunized, four controls) several eggs were unpenetrated but living spermatozoa were present in the perivitelline space or between the cumulus cells, and the remaining eggs had only just been penetrated. Most or all of the eggs would presumably have been fertilized in these mice. A few mice were autopsied 2–3 h after mating for detailed inspection of the uterine contents.

Table 1. DETAILS OF THE IMMUNIZED AND CONTROL MICE

	Group 1*		Group 2*		Group 3*	
	Immunized	Control	Immunized	Control	Immunized	Control
Total No. of mice	9	17	20	13	21	16
No. which mated	8	14	20	13	19	12
No. with all or most eggs fertilized	3+2†	10+2†	9	11+2†	11	8
No. of eggs fertilized	38/48	83/91	74/76	88/105	85/88	54/57
No. with many eggs unfertilized ('partially fertile')	2	1	6	0	5	3
No. of eggs fertilized	3/20	2/7	22/50	–	13/39	8/20
No. with all eggs unfertilized ('sterile')	1	1‡	2	0	3	0
No. of eggs fertilized	0/11	0/8	0/17	–	0/25	–
No. failing to ovulate	0	0	2	0	0	1
No. with eggs activated parthenogenetically	0	0	1	0	0	0

* See text.

† In these mice, active spermatozoa were present among the cumulus cells or in the perivitelline space of many unfertilized eggs, and the penetrated eggs were in the early stages of fertilization. All or most eggs would presumably have been fertilized in these mice.

‡ Spermatozoa were recovered from the uterus of this female. The male concerned was under test at the time of mating, and it was afterwards excluded from the experiment.

Sera obtained from the mice at the time of killing were examined for the titres of spermagglutinins and spermimmobilisins. For spermagglutination, the medium used consisted of equal amounts of medium 199 and phosphate-buffered Hanks's saline (pH 7·1) with a final concentration of 0·1 per cent glucose. For spermimmobilization the same medium plus fresh guinea pig serum as a source of complement was employed. Fresh complement was necessary for this test, the complement being previously titred against mouse spermatozoa to avoid the effects of fresh serum on spermatozoa[4,5]. All tests were read twice. at intervals of approximately 15–30 min and 60–90 min. All sera were coded before the tests, read as unknowns, and decoded after the final titration had been decided.

Of the 47 immunized mice which mated, six ('sterile mice') had unfertilized eggs only, and in 13 others ('partially fertile') more than half of the eggs were unfertilized and living spermatozoa were not found in the perivitelline space of these eggs or between the cumulus cells. No eggs were found in two mice, and one mouse had eggs which had evidently been activated parthenogenetically. Unfertilized eggs were also found in control mice, but more rarely than after immunization (Table 1). The infertility after immunization was not correlated

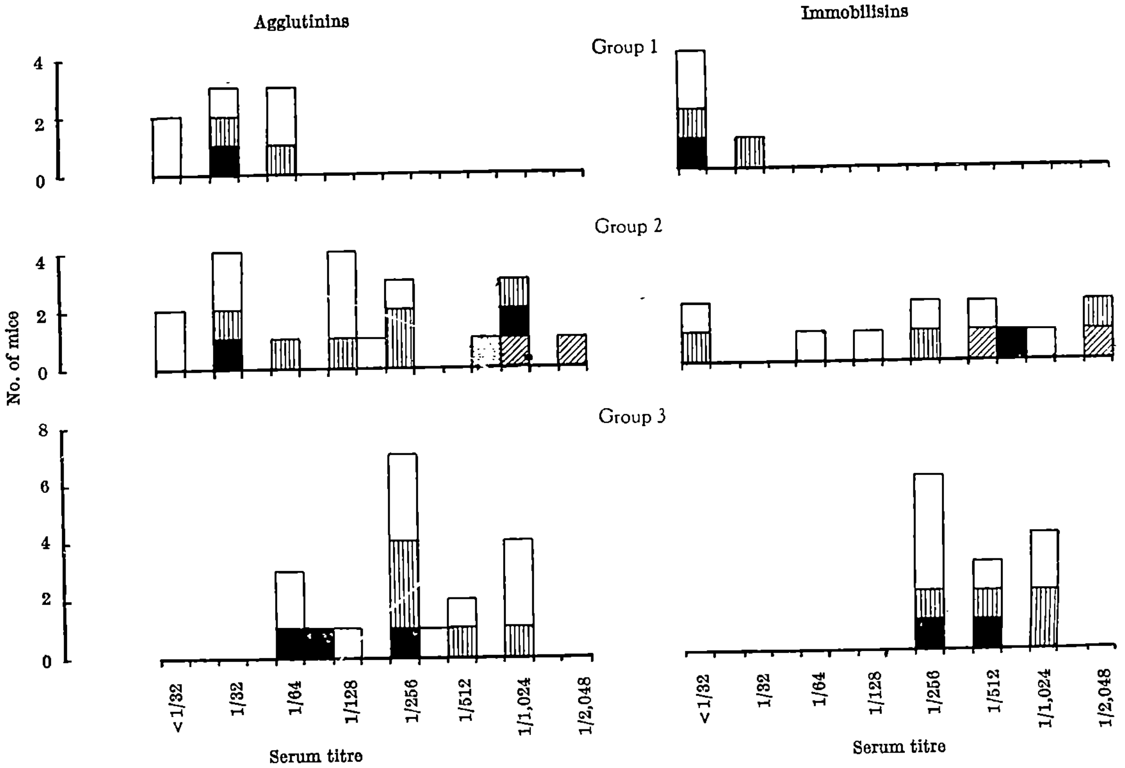

Fig. 1. Relationship between serum titres of spermagglutinins and spermimmobilisins and fertility in the three groups of immunized mice. Black, sterile; vertically hatched, partially fertile; obliquely hatched, failed to ovulate; stippled, eggs activated parthenogenetically; white, most or all eggs fertilized

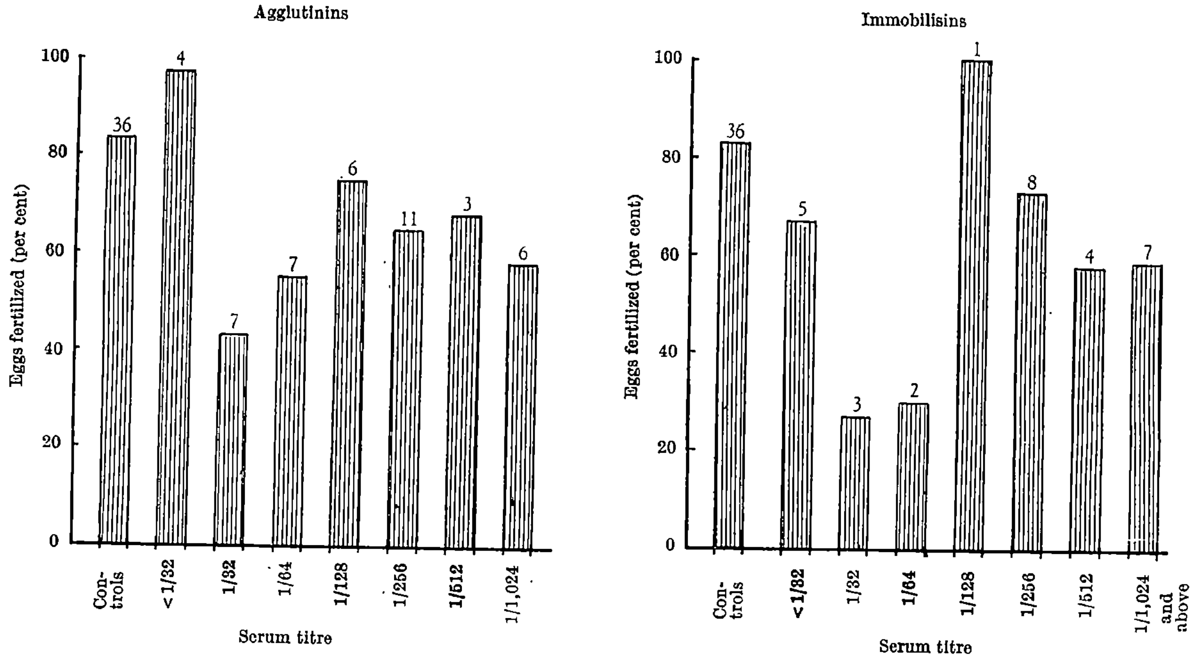

Fig. 2. Relationship between the serum titres of spermagglutinins and spermimmobilisins and the incidence of fertilized eggs. Data from the groups of immunized mice are combined, the numbers of mice contributing to the data being shown in each column

primarily with the titres of circulating antibodies. With one exception, the sterile mice were among those with lower titres (Fig. 1); the exception had high titres, and was the only one of the sterile mice with spermatozoa in the uterus (see following). The partially fertile mice were, in general, among those with higher titres, as were the non-ovulators and the mouse with eggs activated parthenogenetically. But a high serum titre did not necessarily lead to infertility, for all eggs were fertilized in several mice with high titres. The clearest relationship between circulating antibody titres and infertility was found in group 2 (Fig. 1); but this was not confirmed in group 3. When results from all three groups were combined, no consistent trend in the incidence of unfertilized eggs with increasing amounts of circulating antibody could be found (Fig. 2).

Examination of uterine spermatozoa supported the conclusion that circulating antibodies were not necessarily involved in the cause of the infertility. Typical immune spermagglutination was found in none of 36 immunized mice (serum titres between <1/32 and 1/1,024) with uterine spermatozoa. The spermatozoa were clearly separate—more separate indeed than in *in vitro* samples of epididymal spermatozoa—except for occasional large clumps attached by their heads, which is not typical of immune spermagglutination. The absence of agglutination could be especially seen when the uterine spermatozoa were still motile. It is known that antagglutinins in the female tract abolish non-immune head agglutination[6], and agglutination caused by heteroantibodies[7], but we have failed to find such abolition using sperm autoantibodies *in vitro*. Mice with high serum titres of spermimmobilisins often possessed active uterine spermatozoa and/or fertilized eggs, and even the addition of guinea pig complement failed to inactivate the spermatozoa. Serum antibodies thus either failed to reach the uterus or did so in small amounts[8]. The relative absence of serum proteins from the uterus could also be inferred from the remarkable immune-like reactions between spermatozoa and fresh serum from adult animals, which often result in lysis and inactivation of spermatozoa[5].

McLaren's evidence[2] that the numbers of spermatozoa reaching the ampulla are correlated with serum spermagglutinin titre, taken with our evidence of the absence of these antibodies from the uterus, suggests that any effect of these antibodies must be expressed in the Fallopian tubes. Whether the antibodies are secreted into the Fallopian tubes, infiltrate from the peritoneum, or enter with the follicular fluid is not known. Small amounts of antibody in the Fallopian tubes would presumably have a greater effect on fertility than similar amounts in the uterus because the volume of the tubes is considerably less and fewer spermatozoa are found in them. Such a mechanism could have accounted for the infertility in nine of the partially fertile and one of the sterile mice, each of which had high serum titres, many spermatozoa in the uterus, and few or no spermatozoa round the eggs. It seems unlikely that spermimmobilisins are involved, for mouse complement was considerably less efficient than guinea pig complement in immobilization tests *in vitro*. Spermimmobilization and spermagglutination tests evidently measured different antigens on spermatozoa[9], for mice with high serum titres in one test did not necessarily have high titres in the other.

A further cause of infertility was indicated from the examination of the uterine contents of the mice. In our experiments, infertility was evidently associated with the more rapid removal of spermatozoa from the uterus. When uterine spermatozoa were classified as present or absent, and if present as large, medium or small in number, differences became apparent between mice of differing fertility (Table 2). Five of the six sterile mice had no uterine spermatozoa. The somewhat arbitrary classification of mice into those with motile and non-motile uterine spermatozoa also hinted that differences existed between the groups (Table 2). Whether this loss and/or inactivation of spermatozoa was due to induced uterine anaphylaxis[10], to an increased rate of phagocytosis, or some other reason is not known; these effects were certainly not correlated with the titres of circulating antibody. It may not be coincidental that the degree of testicular destruction in guinea pigs and mice after immunization with testis or spermatozoa also bears little or no relationship to the amounts of circulating antibodies[11].

In our experiments, immunization of mice with spermatozoa and adjuvant has not led to drastic reductions in infertility as found by other workers[12] in guinea pigs. It is difficult to make comparisons between species when the

Reactions Between Complex Nuclei

EDITORS: A. GHIORSO *et al.*

This volume contains the papers presented at the third conference and the subsequent discussions. The main topics considered are: elastic and inelastic scattering, stripping, pickup, nucleon transfer and compound nucleus reactions; effects of high angular momentum; Coulomb excitation and nuclear spectroscopy. A summary by J. O. Rasmussen brings the contributions into perspective and relates them to developments since the previous conference. *University of California Press.*

science progress

A review journal of current scientific advance

Every conscientious editor of a scientific journal has to keep asking, "Are we fulfilling our aims?" The editors of *Science Progress*—this year with a completely new cover and layout—are resolute in their efforts to present contributions about actively advancing research, of interest to scientists in many fields: research workers in industry and universities, teachers, students, etc. They intend to resist any trend to publish specialist articles for specialists. These are quite adequately covered by the many advances and reviews sections of journals in all disciplines. The articles in *Science Progress* are written in an easily assimilable form but are more serious than popular science.

The journal emphasizes the spectacular advances resulting from the fusion of scientific disciplines, e.g. physics and chemistry with genetics to give molecular biology, with the aim of stimulating scientists to emerge from their specialized burrows, to appreciate problems in other fields and so to further the unification of science. Book reviews are a special feature of *Science Progress*.

First World Conference on Animal Production
(EFFICIENCY IN ANIMAL PRODUCTION)
Rome, 2nd–7th September, 1963

A number of sets of the Proceedings (four volumes a set) presented at this Conference are available for sale at £5 5s. sterling or U.S. $15.00 per set (postage included).

The Conference was organised by the European Association for Animal Production jointly with the Societies of Animal Production of Australia, Canada, Japan, New Zealand, South Africa and U.S.A., representatives of other regions, and in collaboration with F.A.O., as well as other international organisations. It has been described as the "greatest collection of brains ever assembled in the field of animal science" and the Proceedings include 71 invited papers by world authorities on the following topics :

1. The necessity of defining needs and establishing priorities for solution of animal production problems, taking into consideration the need of human nutrition.
2. Limitations to efficiency imposed by inadequate nutrition with particular reference to feed resources.
3. Influence of breeding on the efficiency of production.
4. Physiological limitations on reproductive performance.
5. The potential for increasing efficiency of feed utilization through newer knowledge of animal nutrition.
6. Basic factors influencing the efficiency of utilization of energy and protein with special reference to their inter-relationship.
7. Improvement of animal production education.

Papers are published in the original language of their authors and are summarized in three others, the official languages being English, German, French and Spanish.

Please send remittances to Dr. Joseph Edwards, Breeding & Production Organisation, Milk Marketing Board, Thames Ditton, Surrey, England.

Dielectrics

Modern Electrical Studies Edited by Professor G. D. Sims

J. C. ANDERSON, M.Sc., Ph.D., A.M.I.E.E., Imperial College, University of London.

Dielectrics, as a subject of study, ranks in importance with semiconductors and magnetism. The last decade has seen many developments in the field of dielectric materials, and this book gives the background theory to them. It is based on the third-year undergraduate course, and on first-year post-graduate lectures delivered in the Materials Course at the Department of Electrical Engineering, Imperial College. **July 1964 28s.**

Biological Control of Insect Pests and Weeds

Edited by **PAUL DeBACH,** Professor of Biological Control, University of California.

A thorough coverage of all phases of biological control of insect pests and weeds. It has been planned for cohesiveness and continuity much as a single author would plan his work. The book is divided into sections whose chapters form a related group of subject matter. The contributing authors are all specialists in their fields and between them have accumulated more than 200 years of research and teaching in biological control work. **July 1964 120s.**

The Principles of Agricultural Entomology

C. A. EDWARDS, B.Sc., M.Sc., Ph.D., and **G. W. HEATH,** B.Sc., Ph.D., Rothamsted Experimental Station.

This book is planned for use by agricultural students, advisory officers, well informed farmers and all who are concerned with pests that attack field crops and stock. The excessive use of technical language has been avoided as far as possible; where it is unavoidable it has been explained. **July 1964 80s.**

METHUEN

NEW HEYWOOD BOOKS

Progress in Semiconductors, Vol. 8

Edited by A. F. GIBSON and R. E. BURGESS

This volume departs from the previous pattern of this international series of critical reviews. Owing to the importance of the subject, the whole volume consists of a review of THE ELECTRICAL CONDUCTIVITY OF GERMANIUM by Dr. E. G. S. Paige of R.R.E., Malvern. The main part of the book examines the extent to which a successful quantitative comparison between experiment and a theory based on the Boltzmann equation can be made. It is preceded by two theoretical chapters building up the elementary theory of galvanomagnetic effects, and it is followed by two chapters extending the theory to include the effects of strain and high electric field.

244 pages, Royal 8vo 70s.

Progress in Cryogenics, Vol. 4

Edited by K. MENDELSSOHN

This well-known series is continued in a new volume with international critical reviews from Great Britain, the U.S.A. and U.S.S.R. The subjects covered are : Radial Flow Low Temperature Expansion Turbines—V. I. Epifanova ; Liquid Helium Supplies in Great Britain—P. L. Smith ; Helium-3 at Low Temperatures—D. F. Brewer ; Ferrimagnetism—R. K. Wangsness ; Magnetic Cooling—W. A. Little ; Superconducting Resonant Cavities—E. Maxwell ; Superconductive Materials and Some of their Properties—B. W. Roberts.

231 pages, Royal 8vo 70s.

Magnetic Tape Recording

H. G. M. SPRATT

The text has been completely revised and reset for this second edition. Particularly valuable are the chapters on tape materials, manufacture and testing. Other chapter headings are : Principles of Magnetism ; Sound Reproduction and Electro-Acoustics ; Principles of Magnetic Recording ; Tape Recording Machines ; Recording and Reproducing Machines for Music and Speech ; Testing of Machines ; Applications of Magnetic Recording ; Present Trends and New Developments. 368 pages, Demy 8vo. 63s.

Obtainable from all booksellers or, in case of difficulty, direct from the publishers: **HEYWOOD BOOKS, TEMPLE PRESS BOOKS, LTD.,** Book Sales Dept., **BOWLING GREEN LANE, LONDON, E.C.1**

Introduction to Biophysical Chemistry

R. Bruce Martin 89s

Within a single volume, this book deals with the properties, function, and interrelationships of the biologically important macromolecules, proteins, and nucleic acids. Throughout, the emphasis is on the end results, and it aims at providing an appreciation of the topics it covers, rather than a detailed analysis.

Radio Ray Propagation in the Ionosphere

John M. Kelso £7

Electronic Sciences Series

The first advanced textbook to give extensive treatment of the geometrical optics of radio signals in the ionosphere. Special features include much material on whistler propagation, and an unusually thorough discussion of the determination of electron density, distribution, ray paths in an anisotropic medium, and to the principal axis equations for ionospheric propagation.

Group Theory and Quantum Mechanics

Michael Tinkham 89s

International Series in Pure and Applied Physics

Presents those elements of group theory essential to physical applications, and gives a brief, systematic treatment of the quantum mechanics of atoms, molecules, and solids, emphasizing the use of group theoretical techniques.

ENGINEERING UNITS and Physical Quantities

H. S. HVISTENDAHL, *B.Sc.(Eng.), M.I.Mech.E., M.I.E.E., M.I.E.E.E.*

A lucid account by a highly experienced engineer of the origins, evolution and present basis of the units used in mechanical and electrical engineering; their nomenclature and symbols according to the latest international agreements, and in particular, conversion factors. These last alone make it a precious work of reference.

128 *pp. Many tables* 25*s*

DIMENSIONAL ANALYSIS

JULIO PALACIOS, *Professor of Physics, University of Madrid*

A capable translation by Dr. P. Lee (Purdue) and Mr. L. Robb (Imperial College, London) of the first book to relate theory to the more recent developments in nuclear physics, quantum theory and relativity; and the first to treat the subject in a general and systematic way. The author faces the differences of opinion that exist today in modern physics and puts them in perspective.

256 *pp.* 42*s*

COMPUTER APPLICATIONS

Edited by ROBERT S. HOLLITCH and MILTON M. GUTTERMAN

This report of the Ninth (1962) Symposium, organized at the Illinois Institute of Technology, is a cogent survey for all who are actually using computers to solve problems in business, management, science and engineering. The contributors discuss both "software" and "hardware" applications, including contemporary and experimental programming languages.

224 *pp. Illus.* 56*s*

NETWORK ANALYSIS for Planning and Scheduling

A. BATTERSBY, *B.Sc., F.R.I.C., Work Study School, Cranfield*

This book draws together the existing knowledge about a rapidly expanding technique for planning and organising large-scale business and industrial projects. It concentrates on the practical aspects of critical path planning and the various modifications such as PERT that have evolved in the last few years. Many interesting examples (including an elaborate train-robbery!).

CLEAVER-HUME PRESS

MACMILLAN

EXTENDED SURFACES

ALLAN D. KRAUS, *Principal Staff Engineer, Honeywell Aeronautical Division, St. Petersburg, Florida.*

The first detailed treatment of an important aspect of heat transfer. It concerns the uses of fins, spines, etc., to cool many kinds of equipment, from missiles and planes to miniaturised electronic components. Many valuable tables of values save the engineer's labour.

288 *pp. illus. about* £5 (*SP*)

STRUCTURAL EFFECTS of IMPACT

M. KORNHAUSER

This rather original treatment places the emphasis on survivability or failure. Though loading and response must be analysed, the author tries to give the engineer some relatively simple approaches to the prediction of failure. Both low speed and hypervelocity effects are considered.

216 *pp. illus. About* 80*s* (*SP*)

ELECTROMAGNETIC ASPECTS of HYPERSONIC FLIGHT

Second Symposium on the Plasma Sheath

Edited by WALTER ROTMAN, HOWARD K. MOORE and ROBERT PAPA

This Symposium, largely Service-inspired, treats of ionized flow fields about aerospace vehicles which can arise from, for instance, shock heating of atmospheric gases during reentry, plume exhausts of both chemical rockets and electrical-propulsion engines, and nuclear and solar radiations.

448 *pp. illus. about* £5 (*SP*)

RUSSIAN MATHEMATICAL SURVEYS

Translation Journal edited by PROFESSOR K. HIRSCH

Queen Mary College, London

Issued by the London Mathematical Society with the support of the D.S.I.R.

Applied mathematicians as well as those concerned with the pure discipline will find much of value in this English version of the Survey Sections of Uspekhi Mathematicheskikh Nauk: there is much on functional analysis and differential equations.

Annual volumes of 6 *nos. each. About* 140 *pages,* £12 *per volume* (*U.K.*) *or* £15 (*overseas*).

Descriptive folder with survey of contents free on request.

Integrating Microdensitometer

The Barr & Stroud integrating microdensitometer measures the optical density of small objects, usually cell nuclei. Using refined techniques, including scanning and electronic integration, it produces extremely accurate results which can be used to calculate the total amount of stained material present.

It has already found application in many laboratories throughout the world. For further details please write for pamphlet 1239c/N.

This unique water still is in use in a number of research establishments and hospitals where water of the highest purity is essential.

PRICE, complete with heater and all electrical equipment 230 volt (a.c. only)—**£30-0-0**
Inclusive of carriage and packing in U.K.

Obtainable only from
L. V. D. SCORAH, M.Sc.
(Manufacturer of the "SCORAH" Blowpipe)

44 NORTHFIELD ROAD, KINGS NORTON,
BIRMINGHAM, 30. KINGS NORTON 1885

The SCORAH Automatic Electric all glass WATER STILL (patented)

Automatic Can be left on without attention. Heater current cuts off if water supply is interrupted, or inadequate or forgotten. When receiver (5 litres capacity) is full, current cuts off. When distilled water is drawn from receiver, the still resumes operation until receiver is refilled.

Purity Electrostatically charged condenser droplets can pick up fumes, dust and air-borne organisms from the laboratory atmosphere. The design of the receiver vessel ensures absence of such contamination.

Efficiency Heater of Scorah design and manufacture, consumption 1,700 watts, output 2.4 litres per hour (the full theoretical yield). Cost 3½d. per gallon at 1d. per unit.

Safety The heating element is out of contact with the feed water, thus eliminating danger from "live" water supply or electrolytic effects or "burn out".

Assembly No retort stands or clamps are required. The 2½-in. diameter ball joint gives a strainless set-up. Outlet cap on boiler for quick periodical drain-off of sediment. The still may be installed on a shelf or platform about 1 ft. above bench level near a sink and enclosed in a transparent plastic cover to keep out dust.
Phoenix heat-resisting glass. Interchangeable ground glass joints.

Motile	12	10	1	0
Immotile	8	12	8	0

* Some mice were not classified.

fertilization rate in the guinea pigs was unknown. The incidence of fertilization in our work was higher and more independent of the amount of circulating antibody than was the incidence of infertility found in mice by McLaren[2]. Differences existed between the two investigations in the immunization procedure, and it is possible that a more effective immune response was produced in McLaren's work by the prolonged intraperitoneal immunization. The high incidence of fertility remaining in mice after immunization indicates that an immunological method using spermatozoa for the control of fertility has not yet been realized.

This work was supported by the Ford Foundation.

CÆSIUM-137 FALL-OUT BODY BURDENS, TIME VARIATION AND FREQUENCY DISTRIBUTION

By WILLIAM H. ELLETT and DR. GORDON L. BROWNELL

Physics Research Laboratory, Massachusetts General Hospital, Boston, Mass.

Any prediction of the hazard associated with fall-out depends on an assessment of both the average level of radioactivity in the exposed population and the variation in body burden between individual members[1,2]. Although results are regularly published on average body burdens[3], the difficulty of providing a sufficiently large sample size has precluded meaningful estimates of body burden variations. We have measured the cæsium-137 content of skeletal muscle samples from 878 persons who died between January 1959 and August 1963 and used the results to test for the likelihood of various frequency distributions.

Of the fission fall-out products, cæsium-137 is an ideal isotope for a study of this type. Because the turnover of cæsium in the body is relatively fast, 50–150 days[4], the adult population is essentially in equilibrium with the radioactivity of its environment. Skeletal muscle contains approximately 60–80 per cent of the body cæsium and is among the organs of highest cæsium concentration[5,6]. Estimates of cæsium-137 body burdens based on measurements of muscle activity agree with those made by means of total body γ-counting[7]. The convenience of counting a γ-emitting isotope allowed us to prepare a large number of samples with minimum handling and attendant risk of sample contamination. γ Spectroscopy on the 662 KeV γ from the barium-137 daughter was used to separate the different radioisotopes in the samples.

Muscle samples weighing 90–140 g were dissected from the thigh or lower abdomen during routine post-mortem operations at the Massachusetts General Hospital. Samples were not collected from patients who had received isotopes for medical purposes or died of highly infectious disease. Frozen tissue samples were dehydrated in a vacuum oven and packed in plastic tubes for counting in a 5 in. × 5·5 in. sodium iodide (Tl) well counter. A technical description of this apparatus has been published elsewhere[6]. For a typical sample the counting error was less than 15 per cent. Following counting, samples were defatted in a 2–1 mixture of chloroform and methyl alcohol and dried to constant weight at 102° C. Final counting data are expressed in picocuries (10^{-12} c.)/g of defatted dry muscle.

To determine how the average level of cæsium-137 activity varied throughout the period of sample collection, the results were averaged in serial sub-sets of 25 samples each. The average sample activity of each subset is shown by the crosses in Fig. 1. The mean sample activity as a function of time, as determined by fitting a fourth order polynomial to the 878 data points, is shown by the solid curve (increasing the order of the approximating polynomial did not significantly change this curve or the subsequent data analysis). The results were also analysed separately for each sex. The mean sample activity per gram of muscle for men was 10 per cent greater than that of women—a difference similar to that previously reported[9]. Since this difference is much smaller than the variability between individuals of the same sex, data for the two groups are combined in Fig. 1.

Following the bomb test moratorium in the autumn of 1958, the body burden of cæsium-137 as reflected in samples collected throughout 1959 was relatively constant. Starting in early 1960 there was a decrease in sample

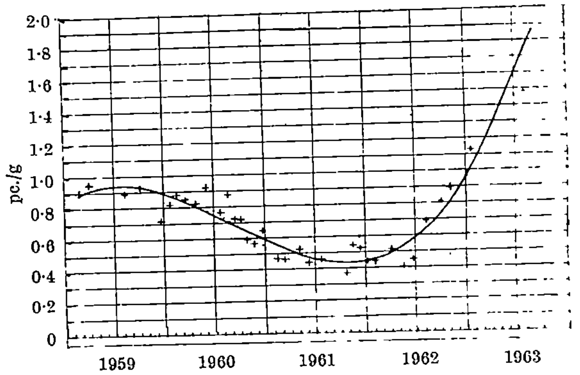

Fig. 1. Time variation of cæsium-137 in muscle. The crosses are average values for serial 25 sample sub-sets. The solid curve is a fourth-order polynomial fitted to the 878 data points

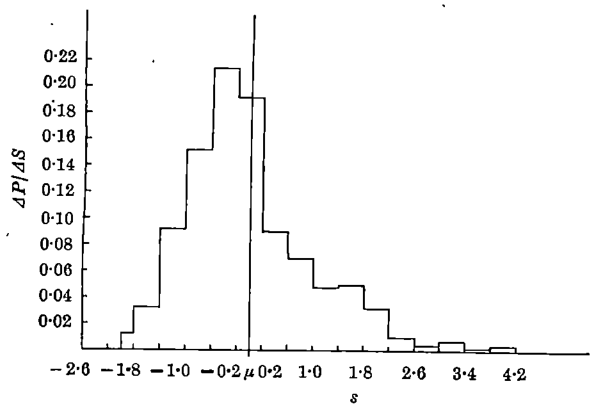

Fig. 2. Probability histogram of the first 670 samples plotted as a function of *s*, the relative standard deviation of the sample. For a normal distribution, the histogram would be symmetric about *μ*, the sample mean

activity which continued until January of 1961. During January 1, 1961–June 1, 1962, the mean levels of cæsium-137 activity in our samples was constant and at a minimum. During this period the average cæsium-137 concentration in muscle, based on 325 samples, was 0·47 (± 0·02) pc./g (dry defatted). This average concentration is probably close to the steady-state value for the amount of fission products, 62 megatons[10], introduced into the environment prior to the test moratorium.

Although atmospheric testing was resumed on September 1, 1961, a rising trend in sample activity was not seen until the summer of 1962. The delay was probably due to a variety of factors such as altitude, at which the nuclear debris was injected, the fact that most crops and fodder had been gathered by September and the time-lag in foodstuff distribution and use. Since mid-1962, the increase in activity has been quite rapid (Fig. 1). This increase will eventually be followed by another decrease as in 1960. If the geographical distribution of the 101 megatons[10] of fission products from the last period of atmospheric testing is not too different from that of tests prior to 1961, the final mean steady-state cæsium-137 concentration in muscle will be about 1·2 pc./g (dry defatted). This will result in an average total body burden of about 8 nc. It is expected that this level will be reached after a transient maximum in 1964–65.

J. Rundo has reported average cæsium-137 body burdens in Great Britain based on total body measurements of potassium-40/cæsium-137 ratios[4]. His results are compared with ours in Table 1. It is seen that the time variation in the two countries was quite similar while the absolute levels in Rundo's group were somewhat higher. Although there is some evidence that cæsium-137 body burdens are higher in Europe than the United States[10a], the difference seen in Table 1 may be due to differences in the two methods of measurement.

Table 1. Comparison of Time Variation of Average Cæsium-137 Body Burdens in Great Britain and North-eastern United States during 1959–63 (nanocuries)

	Rundo U.K.	U.S.A. calculated*		Rundo U.K.	U.S.A. calculated*

* Assuming 63 per cent of the body cæsium-137 is in muscle (ref. 11): both sets of data are for a 70 kg standard man.

Before determining the frequency distribution of the samples, it is necessary to eliminate the time variation by normalizing the data in terms of standard scores. This was done by analysing the data in serial sub-sets of 50 samples each. The variance of each sub-set was calculated about a mean given by the polynomial in Fig. 1, and a histogram of the sub-set prepared in terms of relative standard deviation intervals, *s*. A grand histogram of the first 14 sub-sets, prepared by summing their histograms in terms of *s*, is shown in Fig. 2. The asymmetry of this distribution is obvious; in particular, the number of samples above the $+3s$-level and the lack of samples below the $-2s$-level indicate that these results are not part of a normally distributed parent population. A χ^2 test shows there is essentially zero probability that this sample set was derived from a normally distributed population ($\chi^2 = 200$ for 13 degrees of freedom).

In 1962, Yamagata[11] reported a log normal distribution of natural cæsium-133 in muscle. His results are based on 78 samples, and a visual analysis of a log transformed histogram. We find that most of the asymmetry of the distribution shown in Fig. 2 is removed by a log transformation. However, a χ^2 test on the transformed data gives a probability of less than 1 per cent that the parent population is log normal[12].

Another simple frequency distribution that can be used to describe an asymmetric unimodal data population is the Γ distribution. It has the limits of zero and infinity and is expressed by the function:

$$P(X) = \frac{1}{\beta^{\alpha+1}\Gamma(\alpha+1)} X^{\alpha} e^{-X/\beta}$$

where $P(X)$ is the probability density of a cæsium-137 concentration of X pc./g and α and β are the two parameters which describe a particular distribution. The parameter β serves mainly as a scale factor while α determines the skewness of the distribution[13].

Values of α for each of the 50 sample sub-sets have been calculated from the mean sample activity and subset variance[14]. The results, Table 2, indicate that the values of α are relatively constant and independent of the absolute level of sample activity. The solid curve in Fig. 3 is a histogram of the sample data scaled for comparison with a histogram of a Γ distributed parent population having the same α (ref. 15). A χ^2 test gives a probability of 0·25 that the data are from an infinite set having the same Γ distribution. In Table 2, it is seen that the mean α value for females is less than that for males, and the range of α values is reduced by a factor of 2 when the sexes are analysed separately. Although a *t* test for difference between means gives a 0·15 probability that this difference is due to chance, χ^2 tests show that the results are more adequately described by an appropriate Γ distribution when each sex is considered separately. A χ^2 test on the male data gives a 0·55 probability that it was taken from a parent population with $\alpha = 3·9$. The same test on the female data gives a 0·70 probability that it was taken from a parent population with $\alpha = 3·3$. Since the histogram shown in Fig. 3 ($\alpha = 3·5$) is a summation of two histograms, male and female, normalized to an average mean, the χ^2 probability increases when each set of data is normalized to its own mean.

Table 2. Calculated α Values for Serial 50 Sample Sub-sets

Both sexes and unknowns 878 samples				Males 500 samples		Females 345 samples	
Median time (days)	α	Median time (days)	α	Median time (days)	α♂	Median time (days)	α♀

638	3·7	1,312	7·2	917	3·0	1,264	4·0
692	5·6	1,385	3·0	1,109	3·1	1,476	2·9
738	2·1	1,481	2·6	1,228	4·2		
801	2·4			1,358	4·4		
				1,532	5·1		
	$\bar{\alpha} = 3·5 \pm 0·35$			$\bar{\alpha}$♂ $= 3·9 \pm 0·33$		$\bar{\alpha}$♀ $= 3·3 \pm 0·29$	

We believe the γ distribution can serve as a useful model for the distribution of cæsium-137 body burdens. It has reasonable limits and adequately describes the sample data over the range of observed values. Of particular importance is the observation that α was relatively constant throughout a five-year period in which the mean sample activity varied by as much as 300 per cent. This

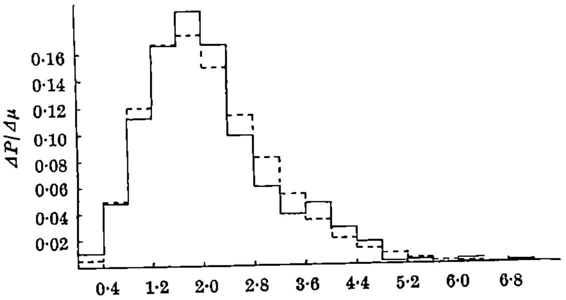

Fig. 3. The solid curve is a histogram of the sample data scaled for comparison with the γ distribution ($\alpha = 3·5$) shown by the dotted lines. The sample mean is at $2·12\mu$. $\mu = X/\beta\sqrt{\alpha+1}$

leads us to believe the Γ distribution can be used to predict what fraction of the population will have N times the mean activity, relatively independent of how this mean varies.

The U.S. Federal Radiation Council has suggested that a factor of three be used in determining permissible total population exposure risks, to allow for variations in individual body burdens[1]. Langham and Anderson[6] have reported that cæsium-137 body burdens are normally distributed, with a standard deviation of 36 per cent, and based hazard predictions on this model. Such a model can seriously underestimate the number of people receiving several times the average body burden. For example, using the model of Langham and Anderson approximately one person per fifty million would have a cæsium-137 body burden which exceeds 3 times the mean. For the asymmetric distribution of body burdens found in this investigation, approximately 75,000 persons per 50 million would exceed this criterion. At the present time, the average body burden of cæsium-137 is small enough that the asymmetry of the frequency distribution is not a critical factor. However, other fission fall-out products, notably strontium-90 (refs. 16 and 17), have similar asymmetric distributions. Depending on the average level of body burdens and the skewness of its frequency distribution, the factor of 3 allowance for population inhomogeneity may or may not be an adequate safeguard for all fall-out products.

We thank Prof. G. Wadsworth, Department of Mathematics, Massachusetts Institute of Technology, for his contributions to the statistical analysis, the Department of Pathology, Massachusetts General Hospital, for supplying the tissue samples, and the U.S. Public Health Service for financial support under grants *Rad C*–2187 and *AM* 05423–03.

COMPARATIVE ROLE OF NITRATE AND MOLECULAR OXYGEN IN THE DISSIMILATION OF GLUCOSE

By PROF. C. M. GILMOUR, R. P. BHATT and J. V. MAYEUX
Department of Microbiology, Oregon State University, Corvallis, Oregon

MICRO-ORGANISMS may utilize nitrate via two markedly different biochemical pathways[1]. For assimilatory purposes, nitrate is routed through reduction to ammonia and appropriate amination reactions to cell protein synthesis. A vast spectrum of micro-organisms is capable of carrying out the foregoing assimilation reaction sequence. However, the dissimilatory route of nitrate utilization involves use of nitrate oxygen as the terminal acceptor of hydrogen and hence acts as the physiological oxidant by which organic substrates are oxidized to produce utilizable cell energy[2]. Thus, the dissimilation of nitrate is termed 'nitrate respiration'.

The quantitative or stoichiometric expression of the participation of NO_3^- oxygen in the catabolism of organic carbon remains to be clarified. Similarly the dual role of molecular and nitrate oxygen as electron acceptors is not understood. It is the purpose of this article to present results which clarify several aspects of the biochemistry of nitrate and molecular oxygen utilization by a typical denitrifier, *Pseudomonas stutzeri*.

A strain of *Pseudomonas stutzeri* isolated from soil was used throughout the work. The culture was maintained by weekly transfers on agar slants consisting of 0·5 per cent potassium nitrate, 1 per cent trypticase (Difco), 0·1 per cent dried yeast extract (Difco), 1·5 per cent Bacto agar (Difco) and distilled water. In all experiments involving glucose utilization the following basal medium was used: yeast extract (Difco), 100 mg; K_2HPO_4, 50 mg; $MgSO_4$ (anhydrous), 3·5 mg; $FeCl_3.6H_2O$ (0·0075 per cent), 1 ml.; MoO_3 (0·0075 per cent), 1 ml.; distilled water, 14 ml. Glucose was added at the rate of 140–180 mg/flask and nitrate at concentrations ranging between 250–1,000 p.p.m. nitrogen.

For obtaining cell yields, the culture was grown on bottle slants at 28° C using the foregoing growth medium. After growth for 36 h the surface cells were removed, washed in phosphate buffer and re-suspended in the basal medium. A uniform cell suspension was obtained by adjusting the cell mass to an optical density of 0·8 using a Bausch and Lomb Spectronic 20 colorimeter at the 630 mμ wave-length.

The electrolytic respirometer assembly described by McGarity *et al.*[3] was used. 100 g of washed sand (20 mesh) was evenly distributed in each 300 ml. respiration flask. The flasks, along with an empty cup in the centre well, were sterilized overnight at 15 lb. pressure. These were then inoculated with 14 ml. of sterilized basal medium containing the required cell mass. 1 ml. of sterile glucose solution brought the sand-medium mixture to 60 per cent of the moisture-holding capacity. 10 ml. of 20 per cent sodium hydroxide was transferred to the empty cup in the centre well of each flask. Then the top joint of the flask was greased and the head assembly put in place. Precautions to avoid contamination were followed, even though the concentrated cell mass minimized this danger. The aerobic sets were attached to the oxygen-generating electrolytic respirometer and flushed with a helium–oxygen (80–20 per cent) mixture for 15–30 min; whereas helium alone was used for anaerobic experiments. All experiments were carried out at a temperature of 28° ± 1° C. In the aerobic experiments oxygen uptake was calculated by noting the volume (ml.) of hydrogen generated and then dividing the latter values by the correction factor of 2. At various time-intervals flasks were taken out to test for nitrogen gas production. Gases evolved were detected using a Beckman *GC*-2 gas chromatograph.

At the end of each experiment the centre well containing the sodium hydroxide was removed and diluted to 100 ml. with carbon-dioxide-free distilled water. Carbon dioxide was determined by precipitation as barium carbonate. After removal of the cup from the centre well, sufficient distilled water was added to each flask to give a 2 : 1 ratio of water to sand. Then the flask was shaken on a New Brunswick type rotary shaker for 30 min at 240 r.p.m. After allowing sufficient time for the sand to settle, the liquid was centrifuged at 2,000–3,000 r.p.m. for 20 min. The supernatant was removed and analysed for residual glucose, nitrite–nitrogen, and nitrate–nitrogen according to standard methods[4–7]. Proper precautions were exercised in all analyses to eliminate the effect of any interfering ions.

The utilization of nitrate oxygen as the terminal acceptor of hydrogen by nitrate reducing and denitrifying micro-organisms represents a rather unique form of bacterial respiration. In such instances, oxidation of the carbon substrate may occur with nitrate as the [O] donor either in the presence or absence of molecular oxygen. However, as is shown in Figs. 1 and 2, increasing the concentration of NO_3^- from 250 p.p.m. to 1,000 p.p.m. results in a progressive decrease in the capacity of the test organism to utilize molecular oxygen. Experiments conducted with 1,000 p.p.m. NO_3^- gave no uptake of molecular oxygen until 36 h had passed. With 500 p.p.m. NO_3^-, a 10–12 h lag in oxygen uptake is apparent, whereas with 250 p.p.m. NO_3^- very little lag is obtained. It is clear that in such experiments we are observing both the simultaneous utilization of nitrate oxygen and molecular oxygen as terminal acceptors of substrate hydrogen; an observation which attests to the probable operation of dual electron carrier systems. In addition, it is evident that high concentrations of NO_3^- either via specific toxicity side-effects or via the preferential use of nitrate oxygen as the terminal acceptor can bring about a complete cessation of molecular oxygen uptake.

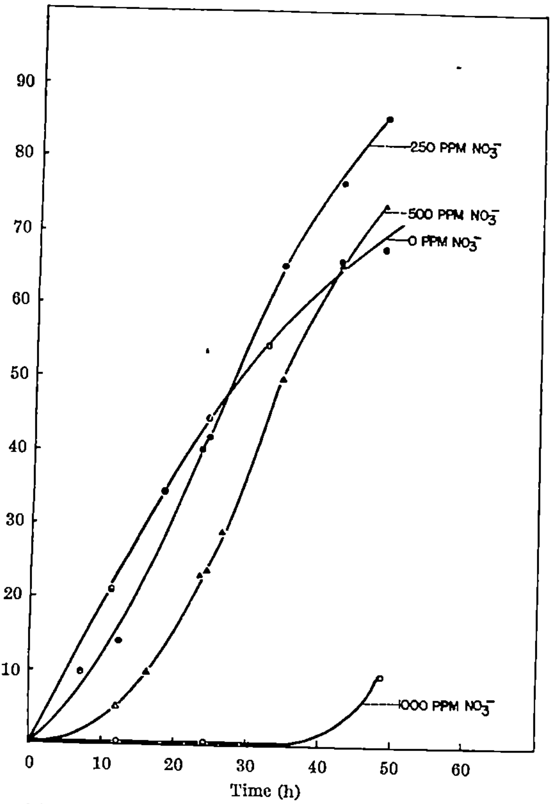

Fig. 1. Oxygen uptake in presence and absence of nitrate

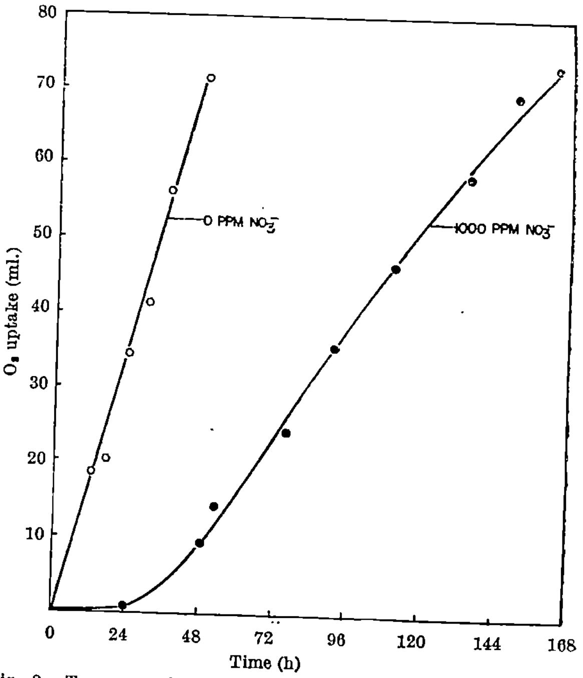

Fig. 2. Temporary inhibitory effect of nitrate on oxygen uptake

The results given in Table 1 show that, as with the decrease in oxygen uptake, there is also a concomitant decrease in carbon dioxide evolution on the addition of nitrate. Here the effect is also reversible, the length of the lag in evolution of carbon dioxide being determined by the concentration of nitrate. Aerobically, at the 48-h interval, we observe a two-fold decrease in millimoles carbon dioxide evolved when comparing 1,000 p.p.m. nitrate with the minus nitrate control sets. On the other hand, at 12 h under aerobic conditions, the 500 and 1,000 p.p.m. NO_3^- sets gave almost identical millimole values of carbon dioxide evolved. As was expected with no nitrate added to the system, the anaerobic examinations showed very low carbon dioxide evolution. A further point of significance of the data given in Table 1 may be obtained by comparing the carbon dioxide values at 250 p.p.m. NO_3^- under aerobic and anaerobic conditions. At the 12- and 48-h time-periods, the millimoles carbon dioxide evolved under anaerobic conditions is approximately half that obtained under aerobic conditions. This observation reflects the dual utilization of NO_3^- and molecular oxygen in the aerobic experiments and the resulting more complete oxidation of the glucose substrate. The lower values obtained for the anaerobic experiments suggests a greater accumulation of metabolic end products or increased assimilation of substrate carbon. Fig. 3 provides added evidence for the latter idea as illustrated by the percentage carbon dioxide produced from glucose at the 12- 24-, 36- and 48-h time-intervals. It is apparent that, with molecular oxygen as the terminal acceptor and no NO_3^- present, the percentage conversion of glucose to

carbon dioxide is much higher than is indicated for 1,000 p.p.m. NO_3^- and molecular oxygen.

At this point in the investigation, it became necessary to ascertain the quantitative use of molecular and/or NO_3^- [O] for the oxidation of each millimole of glucose. Previous data had shown the dual utilization of both sources of acceptor oxygen. It remained to determine the percentage contribution of each oxygen source. An examination of the data in Table 2 provides evidence for the observation that the percentage contribution of NO_3^- oxygen is a linear effect of the degree of suppression of free oxygen utilization by *P. stutzeri*. For example, at 1,000, 500 and 250 p.p.m. nitrate the linear percentage contribution of [O] by NO_3^- is approximately 100, 50 and 25 per cent respectively, at the 12-h period. Between 24 and 48 h, the suppression of molecular [O] uptake is progressively decreased and the linear effect disappears. The lower percentage use of NO_3^- as a terminal acceptor at 48 h for each nitrate-level reflects the removal of the initial nitrate suppression of molecular oxygen uptake and the increased use of free oxygen as the electron acceptor. These data thereby supply further confirmation for the reversibility of the nitrate inhibitory effect on free oxygen utilization.

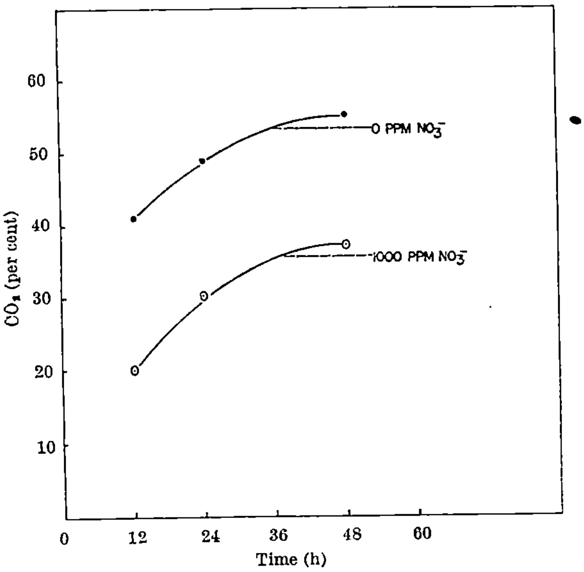

Fig. 3. Percentage conversion of glucose to carbon dioxide

An additional point illustrated by the data in Table 2 (total [O] versus total CO_2) relates to the observed values obtained for total oxygen required for the oxidation of carbon to CO_2; $C + 2\,[O] \rightarrow CO_2$. At 12 h the aerobic system minus nitrate gave an approximate 1 : 1 ratio of [O] to CO_2, thereby falling far short of the theoretical 2 : 1 ratio. It appeared probable that at 12 h the steady state of glucose oxidation had not been attained. However, at 24 h, the aerobic minus nitrate set gave an [O] to CO_2 ratio of 1·6–1 and at 48 h a ratio of approximately 1·8–1. These latter values approach the theoretical ratio of 2 : 1, indicating that in the absence of nitrate *P. stutzeri* quantitatively oxidizes glucose carbon to carbon dioxide and water with little accumulation of other metabolic end products. Similarly at 250 p.p.m. nitrate under aerobic conditions the 2 : 1 theoretical ratio is approached at all time-intervals. However, at 500 p.p.m. nitrate, an approximately 1 : 1 ratio held for 24 h; at 48 h the 2 : 1 ratio is regained. At 1,000 p.p.m. NO_3^-, the aerobic system gave extremely low observed [O] values at all time-intervals. It would appear, therefore, that with the higher (500 and 1,000 p.p.m.) NO_3^- levels a shift in glucose catabolism has occurred in the direction of a more incomplete oxidation of the substrate carbon.

When the data given in Table 2 are calculated so as to equate the total oxygen contributed by nitrate and free oxygen on the basis of glucose carbon oxidized to carbon dioxide, it is then possible to note the quantitative contribution of nitrate according to the following generalized equation:

$$C_6H_{12}O_6 + NO_3^- + O_2 \rightarrow (CH_2O)_n + CO_2 + H_2O$$

These data are shown in Table 3. At 12 h, the total millimoles [O] used gradually decreased from 1·84 at 250 p.p.m. nitrate to 0·32 at 1,000 p.p.m. nitrate. Likewise, at 24 h the total [O] value decreased from 2·32 at 250 p.p.m. nitrate to 0·35 at 1,000 p.p.m. nitrate. As shown previously there was no utilization of molecular oxygen at 12 and 24 h with 1,000 p.p.m. nitrate. It is also evident that the oxygen contributed at the 12- and 24-h periods by the added nitrate is approximately the same, 0·32 and 0·35 millimoles, respectively. It appeared, therefore, that the average value of 0·33 millimoles [O] represented the net contribution of nitrate nitrogen for the production of 1·0 millimole of carbon dioxide. To test this hypothesis, the 0·33 theoretical [O] value was added to the observed molecular [O] value and compared with the actual totals given in Table 3. It became clear that although some variation in the theoretical versus actual observed values was encountered, a remarkably close correlation was obtained; particularly during the steady state of glucose utilization 12–24 h. During the first 12 h the system was somewhat sluggish, and during the 24–48 h period glucose

Table 3. TOTAL MILLIMOLES (O) USED PER MILLIMOLE CARBON OXIDIZED TO CARBON DIOXIDE IN PRESENCE OF NITRATE AND MOLECULAR OXYGEN

Time (h)	NO_3^- (p.p.m.)	Molecular (O)	NO_3^- – (O)	Total (O)	% (O) contribution from NO_3^-–N
12	0	1·03	—	1·03	0
	250	1·31	0·53	1·84	28·8
	500	0·66	0·64	1·30	49·2
	1,000	0	0·32	0·32	100·0
24	0	1·60	—	1·60	0
	250	1·85	0·47	2·32	20·2
	500	0·98	0·37	1·35	27·4
	1,000	0	0·35	0·35	100·0
48	0	1·82	—	1·82	0
	250	1·67	0·18	1·85	9·7
	500	1·90	0·25	2·15	11·6
	1,000	0·98	0·33	1·31	25·6

was depleted with the 250 and 500 p.p.m. sets. Thus it appears that the 0·33 mean millimole [O] value does represent a usable index for *P. stutzeri*. The theoretical relationship can be written as follows:

$$\begin{tikzcd} & \text{Source} \arrow[dl] \arrow[dr] & \\ O_2 \arrow[d] & & NO_3^- \arrow[d] \\ C + 2/3\,[O] & + & 1/3\,[O] \rightarrow 1 \text{ millimole } CO_2 \end{tikzcd}$$

The role of NO_3^- as a donor of [O] in the terminal respiration of facultative anaerobes raises many questions. These relate primarily to the nature of the stepwise reduction of nitrate, the factors influencing nitrate reduction and the fate of the carbon undergoing oxidation. In the work recorded here an attempt is made to clarify certain aspects of the foregoing problem areas.

An initial point involves the dual utilization of NO_3^- [O] and molecular [O]. Since facultative anaerobes such as *P. stutzeri* can grow over a rather wide range in *Eh*, it is considered important to ascertain the extent of utilization of both hydrogen acceptors. The results of the present study establish the point that at low concentrations of NO_3^- both molecular [O] and nitrate [O] are used as final electron acceptors. However, with a concentration of 500–1,000 p.p.m. NO_3^-, there is a progressive decrease in the utilization of molecular [O]. The latter inhibition of molecular [O] uptake becomes a striking characteristic of the entire respiration system and is not easily explained. Toxicity of the formed NO_2^- does not appear to be the answer. Since the inhibition by NO_3^- of both oxygen uptake and carbon dioxide evolution disappears after approximately 48 h, it may be that the inhibition effect centres at some point or sites in the cell enzyme complex. However, as is shown in this investigation, under aerobic conditions NO_3^- [O] is used as the sole acceptor only when high concentrations are used. As the concentration of NO_3^- decreases from 500 to 250 p.p.m., a greater utilization of molecular oxygen occurs. It is evident that if a sufficiently high concentration of NO_3^- is used then a preferential utilization of this acceptor occurs. It may be that the explanation lies in the greater availability to the cell of NO_3^- oxygen versus the rather low concentration of dissolved molecular oxygen. This would clarify the progressive inhibition of oxygen uptake with increasing concentrations of nitrate and would also make plausible any accompanying shift in carbohydrate metabolism. This aspect of the work is now being investigated.

A further point worthy of discussion relates to the stoichiometric expression of 'nitrate respiration'. Over the years investigators have attempted to equate nitrate reduction and carbon oxidation. No definitive results were obtained, particularly in systems containing both molecular and bound NO_3^- oxygen. Yet with facultative anaerobes such as *P. stutzeri* both acceptors must be considered. In this regard, the electrolytic respirometer and companion closed flask assembly used in the present investigation provides an ideal apparatus to examine the aforementioned question. Two questions may be posed: What is the percentage contribution of NO_3^- [O] to the over-all oxidation of the carbohydrate in the presence and absence of molecular [O]? Secondly, what is the quantitative expression of the amount of molecular oxygen or NO_3^- [O] required for the production of one millimole of carbon dioxide? On a strictly theoretical basis, two atoms of oxygen are required to give one millimole of carbon dioxide. For the complete oxidation of one mole of glucose 12 atoms of oxygen are used to give six moles of carbon dioxide (a 2 : 1 ratio). The results given here make clear that *P. stutzeri*, under aerobic conditions, quantitatively oxidizes glucose to carbon dioxide and water with little or no accumulation of other end-products. However, with increasing levels of NO_3^- a progressive decrease in the theoretical [O] to CO_2 ratio occurs, indicating that under conditions of 'nitrate respiration' carbon dioxide plus other end-products accumulate. Here it is possible to observe a shift in carbohydrate breakdown peculiar to the use of NO_3^- as the final electron acceptor.

Of equal interest is the dual operation of NO_3^- and molecular oxygen. Although NO_3^- undergoes only a one-step reduction to NO_2^- in the presence of molecular [O], a considerable contribution is made by NO_3^- to the over-all oxidation of carbon. It appears evident that the one reductive step provides 0·33 millimoles of [O] for each millimole of carbon dioxide evolved. For each millimole of carbon dioxide produced, two-thirds of the total oxygen involved is derived from molecular [O] and one-third from NO_3^- [O]. It is clear, therefore, that with the organism under investigation the quantitative relationship of molecular to NO_3^- oxygen's role as dual acceptors is clarified.

THERMAL EXPANSION OF PYROLYTIC GRAPHITE AND ITS VARIATION DUE TO NON-ALIGNMENT OF THE CRYSTALLITES

By R. H. KNIBBS and I. B. MASON
Atomic Energy Research Establishment, Harwell, Didcot

PYROLYTIC graphite, normally prepared at about 2,200° C, shows a high degree of preferred orientation. However, subsequent heat treatment improves the alignment until, at 3,600° C, the material resembles a mosaic single crystal[1]. Now the thermal expansion of pyrolytic graphite is a property of some interest, since it permits a check to be made of values of the graphite lattice expansion deduced from X-ray diffraction data. It is the purpose of this article to demonstrate, first, that the thermal expansion coefficient of pyrolytic graphite depends markedly on the degree of crystallite alignment, and secondly, that it can be estimated from a knowledge of the degree of alignment and the graphite lattice expansion coefficient.

The material investigated was supplied by High Temperature Materials Inc., U.S.A., in the form of plates 4 in. × 3 in. × 0·25 in. It is understood that these samples

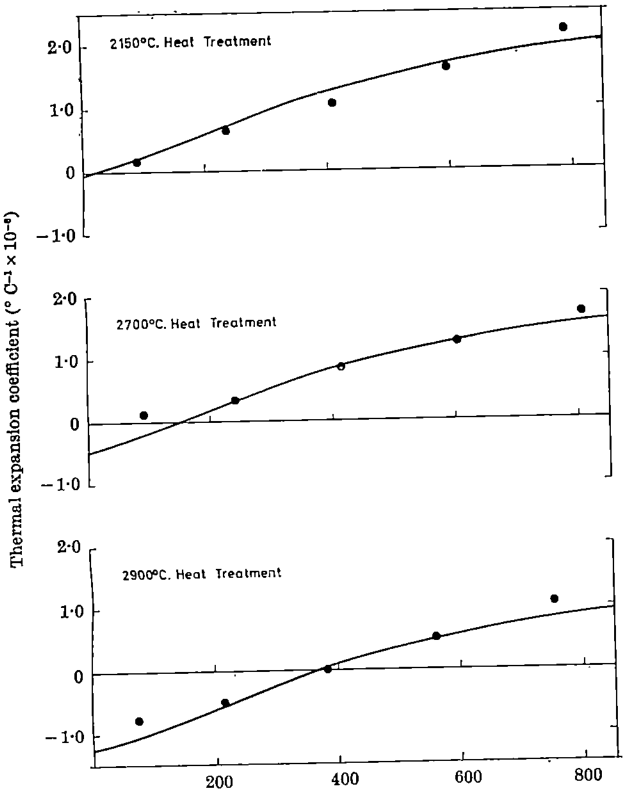

Fig. 1. Variation with temperature of the thermal expansion of pyrolytic graphite heat treated to 2,150° C, 2,700° C and 2,900° C. Measurements made parallel to the planes of deposition
●, Experimental; ——, theoretical

were manufactured at 2,150° C. Specimens were cut and then heat treated to 2,700° C and 2,900° C in an argon atmosphere, the final temperature being maintained for half an hour in each case. Expansion measurements were made over the temperature range 20°–1,000° C using the well-established technique employing tube and push rod, both being made of graphite. Displacements of the push rod were measured using a 'Precimeter' dial gauge. The degree of crystallite alignment was established by the method of X-ray diffraction, these measurements being made by Mr. E. A. Kellett and Mr. C. A. Wallace at the General Electric Co., Hirst Research Centre, Wembley. Measurements were made from forward-reflexion photographs of the tilt angle φ_0 defined as the limiting angular displacement of the crystallite c axes from the normal to the plane of deposition. The full angular distribution was not measured but was estimated in a manner to be indicated later.

The thermal expansion coefficient of a polycrystalline aggregate may, in certain circumstances, be described in terms of the orientation distribution of the crystallites[2]. For a layered structure such as pyrographite, the coefficients relating to directions parallel and perpendicular to the layer planes may then be written:

$$a_{/\!/} = a_a + \left(\frac{a_c - a_a}{2}\right) \cdot \frac{\int_0^{\pi/2} I(\varphi) \cdot \sin^3\varphi \, d\varphi}{\int_0^{\pi/2} I(\varphi) \cdot \sin\varphi \, d\varphi} \tag{1}$$

$$a_{\perp} = \frac{a_c \cdot \int_0^{\pi/2} I(\varphi)\cos^2\varphi \sin\varphi \, d\varphi + a_a \cdot \int_0^{\pi/2} I(\varphi)\sin^3\varphi \, d\varphi}{\int_0^{\pi/2} I(\varphi) \cdot \sin \cdot \varphi \, d\varphi} \tag{2}$$

where a_a and a_c are the graphite lattice expansion coefficients along the a and c axes; the angle φ is measured relative to the normal to the plane of deposition. and $I(\varphi)$ is the number of crystallite axes, per unit solid angle, lying at an angle φ. Use of these functions is justified only if each crystallite contributes fully to the behaviour of the polycrystal, and if there is no interaction between crystallites. It was asumed that pyrolytic graphite satisfied these conditions in view of its near single crystal character.

The distribution function $I(\varphi)$ can be closely approximated for this type of material by $\cos^n\varphi$, where n is an arbitrary parameter[3]. Integration of equations (1) and (2) then give:

$$a_{/\!/} = \left(\frac{n+2}{n+3}\right) a_a + \left(\frac{1}{n+3}\right) a_c \tag{3}$$

$$a_{\perp} = \left(\frac{n+1}{n+3}\right) a_c + \left(\frac{2}{n+3}\right) a_a \tag{4}$$

As n becomes large, equations (3) and (4) simplify to $a_{/\!/} = a_a$ and $a_{\perp} = a_c$, as would be expected for perfect crystal alignment. Values of n were estimated from the values of the tilt angle, φ_0, by adopting the convention that $\cos^n \varphi$ falls to 1 per cent of its peak value when $\varphi = \varphi_0$. The underlying assumption here is that the measured values of φ_0, which can be estimated to within about 1°, represent the true limit of the actual distribution curve. Values of n deduced in this way are given in Table 1, together with values of the tilt angle φ_0.

Table 1. ANGLE OF TILT FOR PYROGRAPHITE OF VARYING DEGREE OF PERFECTION

Treatment temperature (°C)	Tilt angle (φ_0)	n
2,150	41°	19
2,700	30°	32
2,900	8°	475

On substituting known values of a_a and a_c (refs. 4 and 5), $a_{/\!/}$ and $a_{\perp}$ can be calculated using equations (3) and (4). In Figs. 1 and 2 are shown the experimental values of

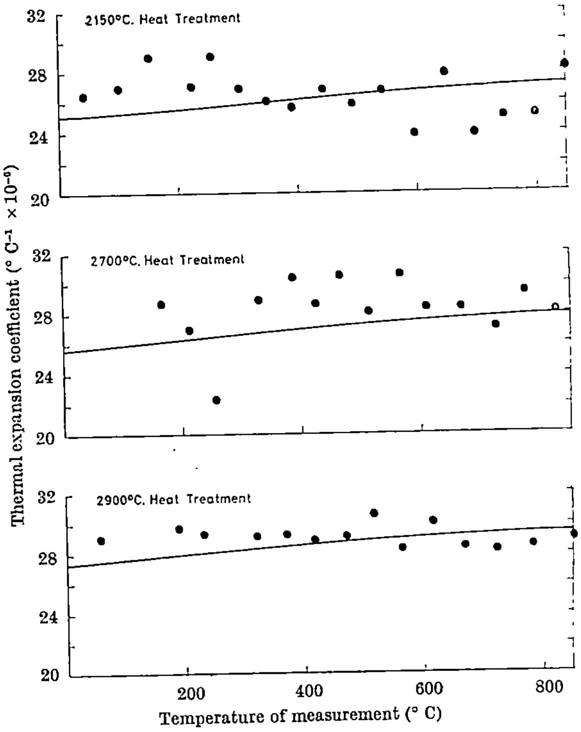

Fig. 2. Variation with temperature of the thermal expansion of pyrolytic graphite heat treated to 2,150° C, 2,700° C and 2,900° C. Measurement made perpendicular to the planes of deposition
●, Experimental; ——, theoretical

the expansion coefficients as a function of temperature, together with curves representing the expected behaviour of the coefficients as derived from equations (3) and (4). It will be seen from the values of φ_0 in Table 1 that the crystallite alignment does not improve rapidly until the treatment temperature exceeds 2,700° C. These changes are reflected in the thermal expansion of the material as illustrated in Figs. 1 and 2, and particularly as measured in the direction along the layer planes. In this respect the 2,900° C material is indistinguishable from a single crystal.

It is concluded that the good agreement obtained between the 'calculated' curves and the experimental values justifies calculations of expansion coefficients of highly oriented materials, based purely on the geometrical distribution or crystallites.

EFFECT OF MANGANESE ON WATER CONTENT OF 'SOLAR' SALT

By Dr. C. SURASITI
Department of Science, Bangkok, Thailand
AND
Prof. E. B. SANDELL
School of Chemistry, University of Minnesota

SODIUM chloride produced by solar evaporation of sea-water at various localities contains varying amounts of included water, ranging from almost none to as much as 20 per cent by weight. We have observed that, in addition to such factors as temperature and rate of crystallization, the presence of manganese in the brine has an important effect on the amount of mother-liquor included in solar salt.

Manganese (II) has been used as an additive to obtain transparent sodium chloride crystals from aqueous solution[1-3] and to produce high-quality salt from sea-water by solar evaporation[4,5]. The addition of 40–500 p.p.m. Mn(II) to brine is sufficient for these purposes. Manganese below this concentration range has been reported to have no effect on the crystallization of sodium chloride[2]. Lead, mercury, cadmium and tin (II) also increase the transparency of sodium chloride[2].

Our observations differ from some reported in the literature. A saturated brine prepared from analytical-grade sodium chloride gave clear crystals even at fairly high rates of evaporation (temperatures up to 50° C), provided that the brine was well stirred; at a moderate rate of crystallization, stirring is not essential. The presence of divalent manganese (0·02–50 p.p.m.), lead (0·4–8 p.p.m.), divalent mercury (2–200 p.p.m.), cadmium (4–100 p.p.m.) and divalent tin (5–600 p.p.m.) in the brine resulted in the formation of mother-liquor inclusions in the crystals. Sodium chloride solutions containing these metals in concentrations outside these ranges gave clear crystals, as did solutions containing other metal ions, except iron (II, III), cobalt, and copper (II), which gave clear crystals in the range 0–5 mM (or up to about 250 p.p.m.).

The liquid inclusions due to manganese, mercury and tin form an hour-glass pattern, the axes of which coincide with the diagonals of the cubes (Fig. 1), indicating adsorption on the 111 planes. The pattern becomes obscured as the number of inclusions increase or the growth rate is high. The same inclusion pattern is found in some solar salt crystals. The inclusions formed in the presence of lead and cadmium are confined to the centres of the crystals, because these ions are so strongly adsorbed by the growing crystals that they are rapidly depleted in the solution[6].

Among the metal ions causing liquid inclusions in sodium chloride crystals, only manganese will be present in sufficient amounts in sea brines to produce a possible effect. It can be derived from the soil of the crystallizing

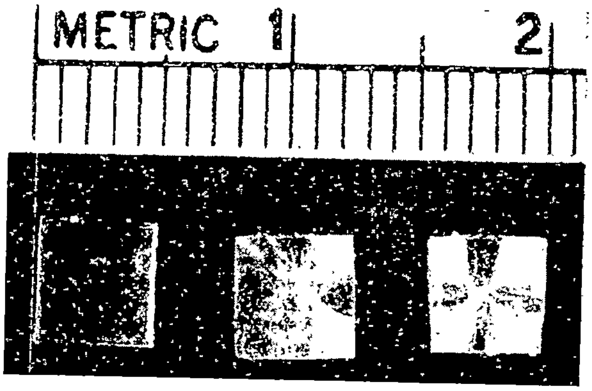

Fig. 1. Sodium chloride crystals grown from well-stirred brines containing 0, 0·02 and 0·4 p.p.m. of manganese (II)

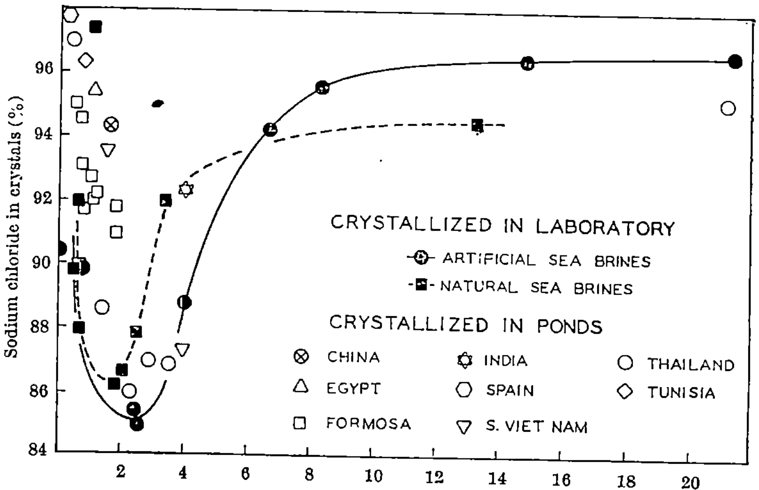

Fig. 2. Relation between manganese content and sodium chloride content of moist sodium chloride crystals obtained by evaporation of artificial and natural sea brines in the laboratory at 50° C and of sea brines in crystallizing ponds under natural conditions

ponds and bio-material as well as from the sea-water. It appears that in the presence of decaying plant material sea-water can extract appreciable amounts of manganese from soil, and this may be the major source of manganese in the brines of crystallizing ponds. As much as 25 and 140 p.p.m. manganese have been found in solar salt and sea brine respectively. Since the quality of solar salt is determined mainly by the amount of mother-liquor retained by the crystals, the manganese content of the brines is an important (but not sole) factor in the quality of the salt they yield.

The effect of trace quantities of manganese on the inclusion of mother-liquor by sodium chloride was studied in the laboratory by evaporating artificial and natural sea brines of varying manganese content at 50° C in 125-ml. Erlenmeyer flasks. The initial volume of saturated brine was 80 ml. and evaporation was continued until 20–30 ml. of water had been lost. The rate of evaporation was approximately 0·3 ml./h. Approximately 10 g of the crystallized salt was washed twice by decantation with 25-ml. portions of a saturated solution of pure sodium chloride and transferred to a Buchner funnel fitted with a filter paper disk. Suction was applied for 5 min to remove as much as possible of the adhering water. The sodium chloride content of the moist crystals was obtained by titrating chloride with silver nitrate and applying a correction for the magnesium chloride present. The percentage of sodium chloride thus found is a measure of the quality of the salt. The deficit, from 100 per cent, represents vacuole water and capillary water between intergrown crystals, as well as water which may be loosely called adhering water. This method is admittedly crude, but it is useful in practice. Manganese was determined colorimetrically with formaldoxime.

Manganese and sodium chloride were also determined in a number of solar salts (first washed with pure saturated sodium chloride solution as described) from a number of countries. The results are plotted in Fig. 2.

Laboratory-crystallized salt from artificial and natural sea brines shows a minimum sodium chloride content when the manganese content of the crystals is 2–3 p.p.m., corresponding to a manganese concentration of 1–4 p.p.m. in the brine. Above and below this value there is a definite decrease in the water content. Solar salts show a similar trend, but, for the same concentration of manganese in the crystals, the included water in solar salt is generally less than in laboratory crystallized sodium chloride. This difference is due to other factors, especially temperature and rate of crystallization, which also affect formation of vacuoles and other imperfections.

THERMIONIC EMISSION AND HEAT OF HYDRATION OF LIME

By A. K. CHATTERJI, T. C. PHATAK and K. D. DHARIYAL
Central Building Research Institute, Roorkee, India

THERMIONIC emission and hydration are two important physical and chemical properties of lime (calcium oxide, a semiconducting oxide). Thermionic emission from lime depends on the position of Fermi-level in it. If hydration of lime were a semiconductor surface reaction, hydration would also depend on the position of Fermi-level and then there would be a connexion between thermionic emission and hydration of lime. It would then be possible to explain the observed peculiarities of hydration of lime, as well as of the effects of impurities, temperature of firing and of particle size on the hydration of lime on a single principle.

Experiments described in this article show that the lower the temperature at which thermionic emission starts for a given sample of lime, the higher is its heat of hydration. Since thermionic emission may occur at a lower temperature if the thermionic work function decreases, the above observation means that the lower the thermionic work function of lime the higher is its reactivity with water. Reactivity of lime with water thus depends on the position of Fermi-level in the lime crystal.

Lime of the following composition (per cent) was used in these experiments: CaO, 89·76; MgO, 0·47; SiO_2 and insolubles, 0·64; Fe_2O_3 and Al_2O_3, 1·67; loss on ignition, 7·56; arsenic was absent. Lime was heated at 850° C for 4 h (1) as it is and (2) with admixture of the following oxides individually: ZnO, Cr_2O_3, NiO, CoO and oxides of molybdenum and manganese. Percentage of CoO mixed was 0·5 and the amount of other oxides mixed was 1 per cent. (Ammonium molybdate and manganous acetate were mixed with lime in calculated amounts and heated and it is presumed that MoO and MnO were formed.) A part of each sample was used for measurement of heat of hydration and a part for electrical resistivity measurement.

Heat of hydration of lime was determined from the difference in the heats of solution of unhydrated and hydrated samples in 6 N hydrochloric acid by the method for the determination of hydration of cements[1,2]. Two determinations of heats of solution of each sample, hydrated or unhydrated, were made and the mean taken. For hydration, a weighed quantity of a sample was mixed thoroughly with 40 per cent by weight of distilled water and was kept in sealed tubes for 7 days at ordinary temperatures. Results are given in Table 1. As lime from the same lot was used and as no sintering was observed on heating with or without oxides, it is presumed that the surface area of lime remained the same in all the samples.

Resistivities of the samples prepared were determined at ordinary and at higher temperatures. For this, about 3 g of a sample was made into a tablet by compressing under a total pressure of 1,000 lb. in a steel mould. Dimensions of the tablets were noted and their resistances at ordinary and at high temperatures were measured, both during heating and cooling, in the manner described elsewhere[3]. No conducting layer was applied on the tablets. Heating rate was 20° C/min, the average cooling rate was 30° C/min, and the specimens were heated up to 950° C. Results of resistivity measurements are given in Figs. 1 (*a*, *b*) (heating) and 2 (*a*, *b*) (cooling), in which $\log_e \rho$ (ρ = resistivity ohm-cm) has been plotted against $10^5/T$ (T in deg. K). Inflexion temperatures in the $\log_e \rho \sim 10^5/T$ curves during cooling are given in Table 1.

Table 1. Heat of Hydration and Temperature of Inflexion of Lime

Serial No.	Sample	Heat of solution of lime (cal./g)	Heat of solution of hydrated lime (cal./g)	Heat of hydration (cal./g)	$1/T$ (inflexion)	Temperature of inflexion (° K)
1	Lime original	805·50	624·20	181·30	0·00119	840
2	Lime heated with 1% ZnO	940·30	651·90	288·40	0·00124	807
3	Lime heated alone	953·50	662·80	290·70	0·00129	775
4	,, ,, with 0·5% CoO	940·57	648·40	292·20	0·00136	735
5	,, ,, ,, 1% Cr_2O_3	936·87	638·74	300·13	0·00145	690
6	,, ,, ,, 1% MoO	942·70	642·37	300·33	0·00148	676
7	,, ,, ,, 1% MnO	945·00	644·65	300·35	0·00145	690
8	,, ,, ,, 1% NiO	970·97	632·76	338·21	0·00160	625

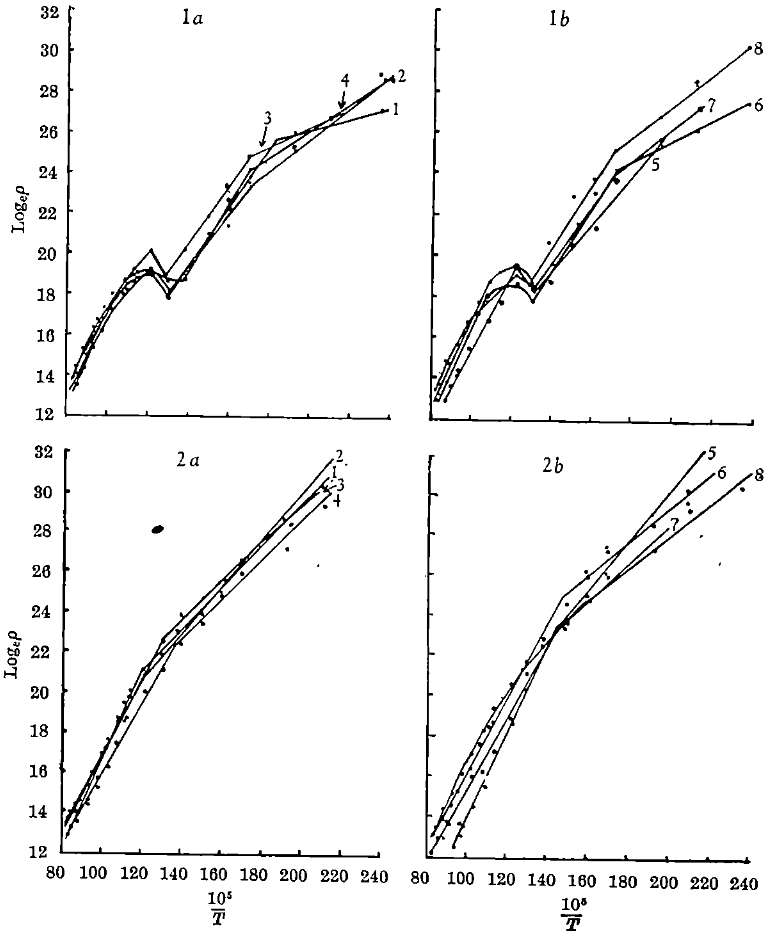
Heat of hydration for lime is given as 276 cal/g (ref. 4). Heat of hydration of the lime as received (lime original, Table 1) is fairly low, indicating that some hydration had already occurred. This is corroborated by the loss of ignition and the break in the resistivity temperature curve (Fig. 1*a*, *b*) at about 527° C during heating. ($Ca(OH)_2$ loses the (OH) groups at about this temperature.) The break in the curves at about 527° C is observed in the heating curves (Fig. 1*a*, *b*) for every sample. This indicates that a certain amount of hydration had taken place during the experiments. A sharp change in slope is observed in some of the curves (Fig. 1*a*, *b*) at about 315° C. This may be the temperature at which adsorbed carbon dioxide escapes completely and so resistivities measured below this temperature are not reliable[5].

Curves in Fig. 2 which represent the variation of resistivity with temperature during cooling show that in general the plots of $\log_e \rho \sim 10^5/T$ are straight lines with a sharp point of inflexion at which there is an increase of slope. This indicates an abrupt additional decrease in resistivity at temperatures higher than represented by the inflexion point. Such plots have been obtained for CaO (refs. 5, 6) and for BaO and BaO–SrO mixtures[7]. Explanation given for such a variation of resistivity with temperature is that, at low temperatures, semiconductivity of the crystallites is responsible for conductivity and at high temperatures the additional conductivity is due to the electron gas in the pores which originates due to thermionic emission from the crystallites[7]. Obviously, the temperature at which the inflexion of the curves occurs represents the temperature at which thermionic emission commences.

Such measurements are taken under vacuum conditions, whereas present measurements were taken in ordinary atmosphere. To see if the explanation offered for the additional increase in conductivity above the inflexion point were applicable in the present case, it is to be noted that the emission of electrons taking place inside the pores is being considered and the external surface of the specimen does not come into the picture, and that the inflexion points, similar to those on cooling, were not observed here during heating. The specimens were prepared under compression and the diameter of the pores must have been very small. The specimens were heated up to 1,223° K. Gas inside the pores had escaped during heating and, at such a high temperature, the probability of escape of gas molecules from the orifice of tube of small diameter is much higher than that of entering it, and the pores, at high temperatures, had been depleted of gas molecules, and adequate vacuum conditions had been obtained and retained during cooling. This may be the reason for the present resistivity–temperature curves (cooling) being similar to those observed by others.

Inflexion temperature for CaO reported in the literature is 625° K[5] and 700° K[6]. Taking the heat of hydration of lime as 276 cal/g, the value closest to this in Table 1 is 288·40 and the corresponding inflexion temperature is 807° K. This means that in the present experiments thermionic emission from the crystallites has started at a slightly higher temperature. That is, some poisoning of the system had occurred.

Table 1 shows that the heat of hydration increases as the temperature of inflexion, temperature at which thermionic emission starts, is lowered. The effect is more



Figs. 1 and 2. $\text{Log}_e\rho \sim 10^5/T$ plots. Figs. 1*a* and *b*, during heating; Figs. 2*a* and *b*, during cooling. Curves 1 and 3 are for lime original and lime heated: curves 2, 4, 5, 6, 7 and 8 for lime heated with ZnO, CoO, Cr_2O_3, MoO, MnO and NiO respectively pronounced as the acidity of the added oxide increases. Lowering of the temperature at which the thermionic emission starts means that the thermionic work function is lowered, that is, the Fermi-level moves closer to the energy level just outside the crystal. Thus the reactivity of calcium oxide with water depends on the position of Fermi-level inside the CaO crystal. The higher the Fermi-level (less the thermionic work function), the greater is the reactivity of lime.

Since calcium oxide is an '*n*' type semi-conductor and since its reactivity with water increases as its Fermi-level is raised, the reaction between calcium oxide and water is an '*n*' type semi-conductor surface reaction. The reaction then takes place through the capture of free electrons from the CaO crystal by the adsorbed water molecules. The nature of this reaction is thus similar to that suggested for the reaction between Portland cement clinker and water[3].

Impurities (SiO_2, Fe_2O_3, Al_2O_3, etc.) as solid solution in lime may raise or lower the Fermi-level of lime and thus affect its reactivity with water. Groups of chemicals which accelerate or retard the hydration of lime[8] may do so by changing the position of Fermi-level by altering the surface charge on being chemisorbed (strong chemisorption) on the lime crystal. The very reaction of lime with water should lower the Fermi-level of lime and hence after the initiation of the reaction it should slow down, that is, there should be an induction period[8]. The effect of firing temperature of lime on its hydration should be governed by the effects produced on Fermi-level of lime as the latter is fired at different temperatures. The effect of particle size of lime crystals on its hydration will be governed by how far the linear size of the crystal affects its Fermi-level.

If the Fermi-level is lowered, heat of hydration of lime becomes less; on the other hand, dehydration of $Ca(OH)_2$ (obtained from CaO with lowered Fermi-level) will be accelerated as the lowering of Fermi-level favours dehydration. Thus, lime of low heat of hydration should, on hydration, dehydrate at lower temperature and vice versa.

It is concluded that: (*a*) The reaction between calcium oxide and water is an '*n*' type semi-conductor surface reaction. (*b*) Reactivity of lime with water depends on the position of Fermi-level inside the calcium oxide crystal—and thus on the thermionic work function of lime. The higher the Fermi-level, that is, the lower the thermionic work function, the greater is the reactivity. Positioning of the Fermi-level in lime crystal is an essential factor in hydration of lime and may be responsible for some of the observed peculiarities of the phenomenon of hydration of lime.

A CASE OF AN INAPPROPRIATE MODEL

By Dr M. HAMMERTON

Medical Research Council Applied Psychology Unit, Cambridge

DURING the early part of this century, three analyses of battle situations were propounded: one by Colonel (afterwards Marshal) F. Foch[1] and two by F. W. Lanchester[2]. The latter have been reprinted by Newman[3], and one of them has recently been given very wide publicity by Hoyle[4]. These models which may be called the N, N^2 and F models, respectively, are of interest, particularly because of the errors they include and exemplify. As such sorts of errors are always likely to occur when mathematical models of complex social situations are constructed, it may be worth while to examine them. Each of these models sought, in effect, to find a measure for the 'value' of a force on a battlefield. Let us state each in turn, and then discuss them critically.

The N model. This, due to Foch, is the least interesting and least sophisticated of the three. Paraphrasing the argument, Foch reasoned that if a force of numerical strength x, the individuals of which had a rate of fire F_x missiles/unit time, attacked a force of strength y, and individual rate of fire F_y, then, if $x > y$, and (as was probable) $F_x = F_y = F$, the 'missile balance' in favour of the attackers in unit time would be $F\ (x - y)$. He concluded that any increase in F must add to the 'balance'; and hence add to the power of numbers, and of the offensive. The 'value' v, of a force, would be shown by:

$$v = kFN \tag{1}$$

where N is its numerical strength and k a constant.

The N^2 model. Lanchester's argument is much more elegant. He supposed that "... each man will, in a given time, score, on an average, a given number of hits that are effective; consequently the number of men knocked out per unit time will be directly proportional to the numerical strength of the opposing forces". Thus, if we express the 'efficiency' (that is, accuracy, etc.) of each unit of the opposing forces by the constant terms a_x and a_y, we have:

$$\left.\begin{aligned} \frac{dx}{dt} &= -\ F_y\, a_y\, y \\ \frac{dy}{dt} &= -\ F_x\, a_x\, x \end{aligned}\right\} \tag{2}$$

Giving, for the reasonably likely case $F_y = F_x$, $a_x = a_y$:

$$x^2 - y^2 = \text{constant} \tag{3}$$

and thence, more generally, that

$$v = k'\ F\ N^2 \tag{4}$$

The F model. Lanchester recognized that his model supposed that individual units were firing at one another, and that this was not always the case. Sometimes enemies simply fired 'into the brown'. In this situation, he reasoned that the rate of loss would be proportional to the rate of arrival of missiles, and to the density of troops on the ground. Thus, introducing another constant term b, being the ratio of the exposed area of a soldier to the area being plastered, the equations derived are:

$$\left.\begin{aligned} \frac{dx}{dt} &= -\ bxF_y\, y \\ \frac{dy}{dt} &= -\ byF_x\, x \end{aligned}\right\} \tag{5}$$

Whence the rate of loss is proportional to the fire-power of the component units, and is independent of the numbers involved. Otherwise:

$$v = k''\ F \tag{6}$$

The model-makers' own assessments. Neither Foch nor Lanchester had any serious doubts of the validity of their theoretical models. In Foch's case this is scarcely surprising; for the argument seems to have been advanced only to support a conclusion already adopted as an article of faith. Lanchester, however, was no less sure that his N^2 model correctly described the contemporary situation. The F model, he rather surprisingly declared, approximated "more closely to the conditions of ancient warfare"; while the N^2 model truly described battle in the twentieth century. He wrote: "Macaulay's lines:

> 'In yon strait place a thousand
> May well be stopped by three'

belong intrinsically to the methods and conditions of the past".

Discussion

(1) *Fighting on land.* If we examine the history of war from 1860 until 1919 (to which period the N and N^2 models were clearly intended to apply) one thing appears to me to stand out: the models are not appropriate. Increases in fire-power overwhelmingly favoured the defence; superiority of numbers on the battlefield displayed nothing like the advantage predicted; it frequently happened that handfuls stopped multitudes. Neither was there anything obscure in this process: it had been quite clear from the happenings of the American Civil War (1861–65), the Franco-Prussian War (1870–71), the Russo-Turkish War (1877–78), the Boer War (1899–1902) and the Russo-Japanese War (1904–5) before the First World War started—and confirmed it. In the first of these struggles it was reckoned that odds of 3 : 1 were often inadequate for victory. In the Boer War, the series of British reverses in 1899 were suffered in spite of favourable odds of more than 2 : 1. The grisly series of western front battles in the First World War bloodily underlined the lessons of the previous decades: throughout 1917, for example, the Allies in France had an overall superiority of about 3 : 2, and often more on the actual battlefield[5]. Since the mathematics is sound, then, where did the assumptions err?

Perhaps, instead of sniping at Macaulay, Lanchester should have remembered the line from a well-known, though rarely printed, limerick:

> "Who does what? And with which? And to whom?"

For a built-in assumption is that both parties are doing the same sort of thing. This is very rare indeed in war. Suppose that, still in the range of ultra-simple models, we remedy this. Let us imagine a 'Boer War' situation: force x is attacking force y, the men of which are snugged down among rocks and entrenchments. Then the riflemen of force x are under fire as individuals, as in the first equation of (2); but the y position is merely being plastered, as in the second equation of (5). The loss rates are then (again supposing $F_x = F_y = F$)

$$\left.\begin{aligned}\frac{\mathrm{d}x}{\mathrm{d}t} &= -\,Fa_y y\\ \frac{\mathrm{d}y}{\mathrm{d}t} &= -\,Fbyx\end{aligned}\right\} \tag{7}$$

whence

$$bx^2 - 2ay = \text{constant} \tag{8}$$

It is immediately evident, without even noting that, for example, $a \gg b$, that no 'value' term can be put on a force without first asking: what is it trying to do? And even this slightly more realistic expression leads to some very odd conclusions (the reader can play with them himself) as x and y become very large. These arise from two more built-in assumptions, namely, (i) (as in (2)) every component unit of x can shoot at any component unit of y; and (ii) (as in (5)) there is no limit to the density of force in a given space. It is obvious that both these assumptions will, in general, be false. (Parenthetically, it may be remarked that the F model, though it looks a trifle odd, is not a bad one in some special cases.)

(2) *Fighting at sea.* The built-in assumptions which we have noted in the N^2 model were most nearly satisfied by naval fighting during the heyday of the battleship, say from 1890 to 1917. Indeed, the valid application of the N^2 law was, perhaps, never better demonstrated than at Tsu-Shima (1905). It also explains many of the manœuvres at Jutland (1916)[6]. However, even at sea, the assumptions are not generally valid. For example, throughout the age of sail, gun ranges were so short that it was not possible to bring the fire of more than a few ships to bear on a single enemy ship, however many were available. This brings us to the historical case cited by Lanchester.

(3) *Trafalgar.* Lanchester claimed that Nelson showed an intuitive understanding of the N^2 law by his tactics at Trafalgar. In particular, he cited the famous memorandum, in which Nelson discussed the hypothetical case of a British fleet of 40 sail tackling a Franco-Spanish fleet of 46. Here he devised a plan to bring 32 British ships against 23 enemies, while the remainder were held in play. But in the actual battle, what did Nelson do? In the event, his lee division of 15 ships under Collingwood took on 15 of the enemy; and he was pleased enough with this to call it 'magnificent'. His own weather division of 12 ships also tackled roughly equal numbers. Before he sailed, he told a friend that he wished to bring on "a pell-mell battle". He was ready and anxious to do this because he was justly confident that, so superior were his crews in gunnery and seamanship, that they could be relied on to win single-ship actions, so long as the enemy could be made to stay and fight it out. His great problem was not to secure a fight at numerical advantage; it was to compel a fight to a finish. This was difficult, and his solution brilliant, because all naval actions in the age of sail were fought in an effectively anisotropic space. Because of the wind, the time taken to get from A to B was not, generally, the same as that taken to get from B to A. This, however, is quite another story[7].

Nothing that has been written here contradicts in any way the common-sense notion that superior numbers are, as a rule, advantageous and sometimes decisive. (Not always: they may be more difficult to control, or to supply, or they may offer too dense a target, and so on.) Neither does it bear on the utility of the whole-versus-part stratagem, which has been successfully used on scores of occasions throughout history. We have, however, underlined how misleading, and potentially disastrous, it can be if a mathematical model is applied to a real situation which it does not truly represent. All mathematical models must simplify: that is their strength. They may, in over-simplifying, distort: that is their danger.

Perhaps the moral was stated—as so often—by the Jeffreys[8]: "One often sees a statement that some result has been rigorously proved, unaccompanied by any verification that the conditions postulated in the proof are satisfied in the actual problem—and very often they are not. This misuse of mathematics is to be found in most branches of Science"; and, I may add, it is especially seductive in the sciences which deal with human behaviour. I may also add: exercise extreme care when citing historical examples.

RADIOPHYSICS

OH Absorption Spectra in Sagittarius

We have measured the 18-cm OH absorption spectrum of Sagittarius *A* over a range of 6·4 Mc/s using the 60-ft. radio telescope of Harvard College Observatory. This frequency range covers both the 1,667 Mc/s $F(2 \rightarrow 2)$ and the 1,665 Mc/s $F(1 \rightarrow 1)$ transitions. The spectrum is dominated by two features at +40 km/sec and −120 km/sec with respect to the local standard of rest. Parts of this spectrum have been previously reported[1–3], notably the feature at +40 km/sec[1]. We have also obtained an absorption spectrum for $l^{II} = 4°$, $b^{II} = 0°$. The characteristics of the background continuum radiation near 18 cm and this absorption spectrum allow us to establish an upper limit on the state temperature of interstellar OH.

The spectrum shown in Fig. 1 covering a range of velocity of several hundred km/sec has been obtained in the direction of the strong radio source Sagittarius *A* with 80 kc/s filters. The antenna temperature of Sagittarius *A* as determined by declination scans is 45° K. We find two broad lines at radial velocities of +40 km/sec and −120 km/sec. The characteristics of these lines are given in Table 1. No attempt has been made to investigate the previously detected narrow lines at 0 km/sec and −50 km/sec[4]. We find an apparent intensity ratio of the $F(2 \rightarrow 2)$ transition to the $F(1 \rightarrow 1)$ transition of 1·2 ± 0·1 for the +40 km/sec and of 1·5 ± 0·1 for the −120 km/sec line. The ratio for the +40 km/sec line agrees with that obtained by Robinson *et al.*[4].

For both +40 km/sec and −120 km/sec lines we have determined a mean separation between the $F(2 \rightarrow 2)$ and $F(1 \rightarrow 1)$ components and find a value of 1·96 ± 0·04 Mc/s. This experimentally observed separation is in good agreement with the difference in rest frequencies of 1·955 Mc/s as determined by Weinreb *et al.*[5]. The velocity range of the OH absorption measurement in Sagittarius *A* lies within the range where hydrogen has been detected and which has been assigned to regions near the galactic centre by Oort and Rougoor[6].

In order to convert the apparent depths of the absorption lines to optical depths, it is necessary to make some assumptions about the background radiation and the angular size of the absorbing region. Robinson *et al.*[4] have suggested that there is evidence that the OH cloud at +40 km/sec has an angular size less than 4 min of arc. We evaluate the partial contribution to the total antenna temperature due to the core source behind the OH by scaling the value quoted by Robinson for the 210-ft. antenna (135° K) to the value applicable to the 60-ft. antenna. Based on a measured collecting area of 95 m² for the 60-ft. antenna and an assumed cross-section of 1·6 × 10³ m² for the 210-ft. antenna, we adopt a value of 8° K for the contribution of the core.

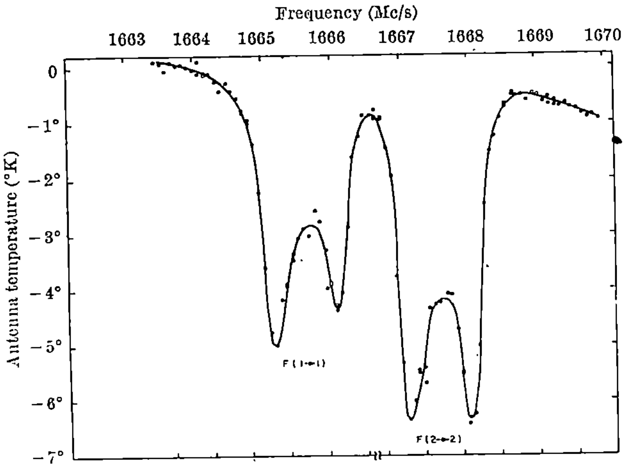

Fig. 1. OH absorption spectrum of Sagittarius *A* showing both transitions. Velocities are relative to the local standard of rest for each transition. The zero point of the temperature scale is arbitrary. The line is a free-hand fit to the data points. Each point represents an integration time of 480 sec

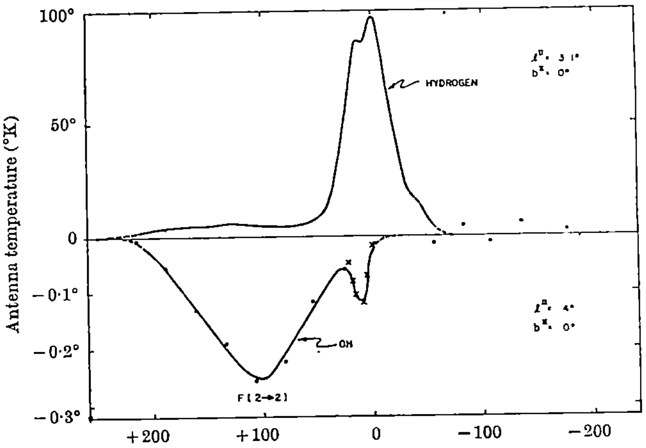

Fig. 2. A comparison of the Leiden HI emission profile for $l^{II} = 3·1°$, $b^{II} = 0°$ with the OH absorption profile for $l^{II} = 4°$, $b^{II} = 0°$ on the same velocity scale. Note the difference in temperature scales. The open circles are measurements made with 150 kc/s filters and an integration time of 1,400 sec; the crosses are measurements made with 25 kc/s filters and an integration time of 25,000 sec

For the +40 km/sec component we then obtain a τ of 1·4 for the $F(2 \rightarrow 2)$ transition and 0·95 for the $F(1 \rightarrow 1)$ transition, giving a ratio of 1·5. Considering the difficulty of assigning an exact value to the antenna temperature due to the core source, the difference between the computed value of 1·5 and the predicted value of 1·8 may not be significant. In view of the evidence of a peculiar spatial distribution of the OH in the +40 km/sec cloud, and recognizing that a similar situation may exist at −120 km/sec, we have not attempted to obtain a solution for the opacity at −120 km/sec.

The limits in velocity published by Robinson *et al.* for the +40 km/sec line[4] are −60 to +100 km/sec. They did not report the −120 km/sec line. It is possible that the −120 km/sec feature lies outside the beam of the 210-ft. antenna when directed toward Sagittarius *A*.

Table 1

Velocity (km/sec)	ΔT (° K) 1,667	1,665	Half-width (km/sec)
+40	6·0 ± 0·2	4·9 ± 0·2	86 ± 6
−120	6·0 ± 0·2	4·1 ± 0·2	76 ± 6

The spectrum at $l^{II} = 4°$ shown in Fig. 2 was made with filters having band-widths (to half-power points) of 150-kc/s spaced 150 kc/s. Two features are evident. One is a broad absorption line with a width of 100 km/sec, a depth of 0·25 ± 0·1° K and a shift of +110 km/sec with respect to the local standard of rest. A narrow absorption line having a width of 15 km/sec, a depth of 0·09 ± 0·03° K superimposed on the broad feature, and a shift of +10 km/sec was observed with 25-kc filters spaced 25 kc. The broad line coincides in velocity with the long wing of the hydrogen emission profile at nearby positions[7,8]. We have checked these results by observing the $F(2\rightarrow2)$ and the $F(1\rightarrow1)$ transitions for both features.

We measured the 18-cm continuum radiation at $l^{II}=4°$, $b^{II}=0°$ with respect to the points about 10° above and below the plane. We obtain $8° \pm 2°$ K for the increase in antenna temperature. The position $l^{II}=4°$, $b^{II}=0°$ was selected because it is a broad local minimum of continuum emission in the galactic plane, and provides an approximately uniform background brightness temperature over our antenna beam (52′)[9-11]. The occurrence of absorption lines allows us to place an upper limit on the state temperature of about 10° K; this is a direct result not dependent on assumptions about the optical depth as is the case with all previous estimates.

The radiometer used compares the available power from the antenna to that from a liquid-helium cooled resistor in ten frequency bands at the same time. The first amplifier is a cavity maser similar to the 21-cm maser[12] which has been used for hydrogen-line observations at Harvard since 1960. The system noise temperature neglecting the contribution due to the source is 110° K when the bandwidth is 2·8 Mc/s.

We thank Prof. N. Bloembergen for help with the development of our equipment. This work was supported by the U.S. National Science Foundation with the assistance of Bell Telephone Laboratories, Inc.

Lightning Flash Counts and Radio Noise Fields in the Tropics

IT is now generally accepted that the source of atmospheric radio noise is the natural lightning discharge associated with thunderstorms, the discharges possessing energy components throughout the radio-frequency spectrum[1]. It is, therefore, to be expected that a correlation exists between the measured level of noise fields and the frequency of occurrence of lightning discharges in a given area. A standard lightning flash counter has been adopted by the International Radio Consultative Committee (C.C.I.R.) for obtaining statistical data about lightning flashes at various locations throughout the world[2]. The Central Radio Propagation Laboratories of the United States (C.R.P.L.) and the Radio Research Board of the Department of Scientific and Industrial Research of Great Britain (D.S.I.R.) have designed two separate equipments for the measurement of atmospheric noise-levels, and these have been installed at chosen sites over the world. Fortunately, a standard lightning flash counter and one each of the noise recording equipments were kindly made available at Ibadan, Nigeria (7° 26′ N, 3° 54′ E.), in the tropical belt during and after the International Geophysical Year, thus facilitating the collection of a fairly large amount of statistical data for lightning flash counts and median values of noise power.

The effective range of the lightning flash counter is 30 km with a probability of 90 per cent; and the triggering is at a step function voltage of 3 V, the equivalent field strength at the aerial 7 m high being about 3 V/m. The flash counter was operated at very low frequencies, but since both ground and cloud flashes are considered, its response is over a wide bandwidth extending from 1 kc/s to over 30 kc/s. The median values of noise power referred to 1 kc/s bandwidth for seasonal blocks (one season and one of six 4-h time periods of day as recommended by the C.C.I.R.)[3] have been compared with the mean values of number of lightning flash counts per h for corresponding seasonal blocks. The comparison has been based on long-term rather than hour-by-hour comparison since the world-wide predictions of atmospheric noise levels[3] are made for seasonal blocks only. The field values used in the comparison have been restricted to 24 kc/s and 51 kc/s, being the lowest frequencies available on the D.S.I.R. and C.R.P.L. equipments, respectively. Fig. 1 presents the variation of measured noise field at 51 kc/s in F_a, expressed in db. above kTB (the thermal noise power in watts in a passive resistance) on linear scale where: k = Boltzmann's constant = $1{\cdot}38 \times 10^{-23}$ joule/°K; T = absolute temperature in deg. K (290° K); B = effective noise bandwidth (c/sec); with the mean counts per h (on logarithmic scale). The values plotted here are the medians of noise fields for all the seasons of the year and the count per h has been averaged for all the seasons. Fig. 2 presents similar results at 24 kc/s for the spring season only.

The 'best fit' lines have been drawn on Figs. 1 and 2 and the derived equations which best suit the relationships are:

$$F_a = 130 + 17{\cdot}5 \log_{10} n \ (24 \text{ kc/s})$$

and

$$F_a = 113 + 18 \log_{10} n \ (51 \text{ kc/s})$$

Apart from the expected difference in the magnitude of field values at the two frequencies, the two relationships are similar in that they have the same exponential form.

An attempt has already been made to compare the noise field and mean counts per hour from a similar 3 V, 7-m aerial, C.C.I.R. lightning flash counter at Singapore, Malaya (1·3° N., 103·8° E.), also in the tropics[4]. A similar C.R.P.L. noise-recording equipment was used to obtain noise fields at a low frequency of 13 kc/s. In the Report of Study Group VI of the C.C.I.R. Tenth Plenary Assembly in 1961, the relationship that closely agreed with observed results at Singapore is that:

$$F_a = 28 + 10 \log_{10} (nW/f^2)$$

where W = total energy in a single atmospheric in a speci-

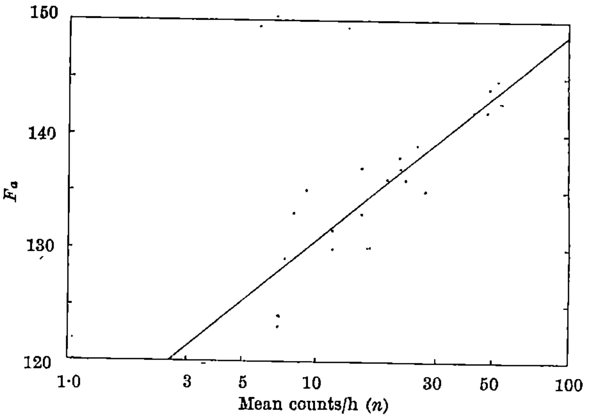

Fig. 1. Lightning flash counts and noise fields at 51 kc/s for all seasons

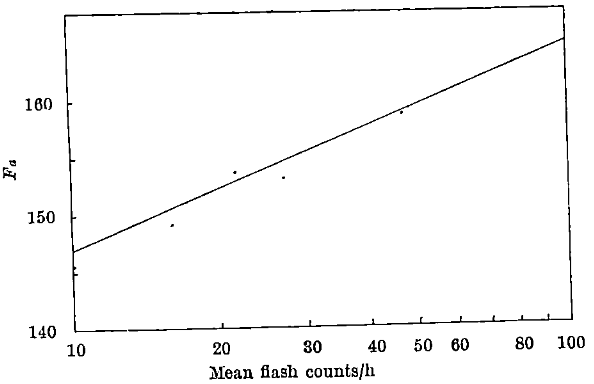

Fig. 2. Lightning flash counts and noise fields at 24 kc/s for spring only

fied bandwidth and taken as 3×10^8 $(\mu V/m)^2$ sec in a bandwidth of 1 kc/s. (The value was that obtained in Slough, England, in a temperate area and assumed here for the tropical areas.) f = frequency (Mc/s).

For direct comparison between the results from observations at Singapore and Ibadan, correction has been made at Ibadan for differences between the tuning frequency of the flash counter and 24 kc/s and 51 kc/s, respectively.

Hill[5] discussed the theory of the generation of low-frequency electromagnetic radiation by cloud-to-ground lightning strokes and predicted the spectral intensity of total radiation from the return stroke as:

$$R = 8 \times 10\ F(\gamma)\ \text{joules/(kc)}$$

where $\gamma = 0{\cdot}19\, f_{\text{kc/s}}$.

The function $F(\gamma)$ has the form:

$$F(\gamma) = \gamma^{-4}\ (\sin\gamma - \gamma\cos\gamma)^2$$

The maximum point of the spectral distribution lies at 11·2 kc/s, and the total width at half maximum is 12 kc/s. From the power attenuation with respect to maximum at the frequencies considered and the response curve of the flash counter, appropriate corrections are applied to the relationship of the Study Group which reduces to:

$$F_a' \simeq 130 + 10\log_{10} n\ (24\ \text{kc/s})$$

$$F_a' \simeq 110 + 10\log_{10} n\ (51\ \text{kc/s})$$

which show closer similarity to the suggested relationships for Ibadan. A significant difference, however, lies in the exponential part. Whereas the results from Singapore suggest that F_a varies as $\log_{10} n$, the results at Ibadan indicate variation with $\log_{10} n^{(1{\cdot}75-1{\cdot}80)}$. This leads to the suggestion that a more accurate law of variation in a tropical area should be of the form:

$$F_a = 28 + 10\log_{10}(n^{\alpha}\ W/f^2)$$

and at Ibadan, a value of approximately 2·0 is suggested for the exponent α. The plots for 51 kc/s (Fig. 1) at Ibadan have been averaged over all seasons of the year whereas those for 24 kc/s (Fig. 2) have been averaged over one spring season. I have already indicated that the spring season is the most intense for lightning activity at Ibadan[6]. The relatively wide scatter in Fig. 1 indicates that the relationship between lightning intensity and noise field should preferably be expressed over one seasonal period only; and that the exponent α has seasonal variations probably arising from slight seasonal variations in the structure of lightning discharges and seasonal changes in the relative contribution of local flashes to the total noise intensity.

As already pointed out[7], the meteorological thunderstorm day suffers from a number of deficiencies when used as a symbol of spherics activity; and cannot be used as indication of noise-levels. The investigation described here confirms that in areas where storms are prevalent, the noise power at low frequencies bears a direct relation to the density of lightning flashes, and at these frequencies the rate of occurrence of lightning discharges will assist in more accurate predictions of atmospheric noise levels for aiding radio communication from one place to the other on the Earth's surface. Further investigation, however, is necessary at many more locations, especially in tropical areas, to ascertain the dependence of the exponent α on time of day, season of year, geographic location and frequency.

GEOPHYSICS

The Satellite Geoid and the Structure of the Earth

COOK[1] has shown that, in the Earth's gravitational potential when developed into a series of zonal spherical harmonics, the coefficients are influenced to the fourth harmonic by the inhomogeneities of the inner core; the inhomogeneities of the outer core will appear at first in the coefficients of $n = 5$–11.

Shortly after this communication, Izsák's communication appeared[2] giving the details of a satellite geoid determined by the coefficients of zonal and tesseral harmonics up to an order of 4.

Cook's results suggest, however, that the general form of this fourth-order geoid must have a source in the inhomogeneities near the core of the Earth.

Vogel[3] has shown on the basis of *PcP*, *ScS*, *PcS* and *ScP* waves that on the surface of the outer core undulations with amplitudes up to 200 km exist.

Vogel's results plotted in a simplified way on the map of a satellite geoid (namely, denoting the spots at normal depth by 0, below the average depth by −, above the average depth by +) show the surprising result that the undulations of the core (where data exist) are followed by the undulations of the satellite geoid.

As a generalization of Cook's theorem, it may be concluded that the undulations of the geoid are caused by undulations on the surface of the outer core.

It may be shown that the gravitational effect of mass inhomogeneities observed in the form of undulations of the core yields the undulations of the satellite geoid with a right order of magnitude.

The core undulation below a certain geoid undulation can be approximated by a sphere of a diameter of 200 km, if it is supposed that the effect of the other core undulations are compensated by each other. The undulation caused on the geoid may be computed by the quotient of the sphere's gravitational potential and gravity acceleration on the surface: $h = \dfrac{W}{g}$.

Denoting by $R = 10^7$ cm the radius of the sphere approximating the core undulations, $\rho_1 = 5{\cdot}7$ g cm^{-3} the density on the bottom of the mantle, $\rho_2 = 9{\cdot}7$ g cm^{-3} the density on the top of the core, $r = 2{\cdot}8 \times 10^8$ cm the average distance of the sphere approximating the core undulation from the surface, and $g \cong 10^3$ cm sec^{-2} the gravity, then

$$h = \frac{4\pi f R^3(\rho_2 - \rho_1)}{3rg} \cong 40\ m$$

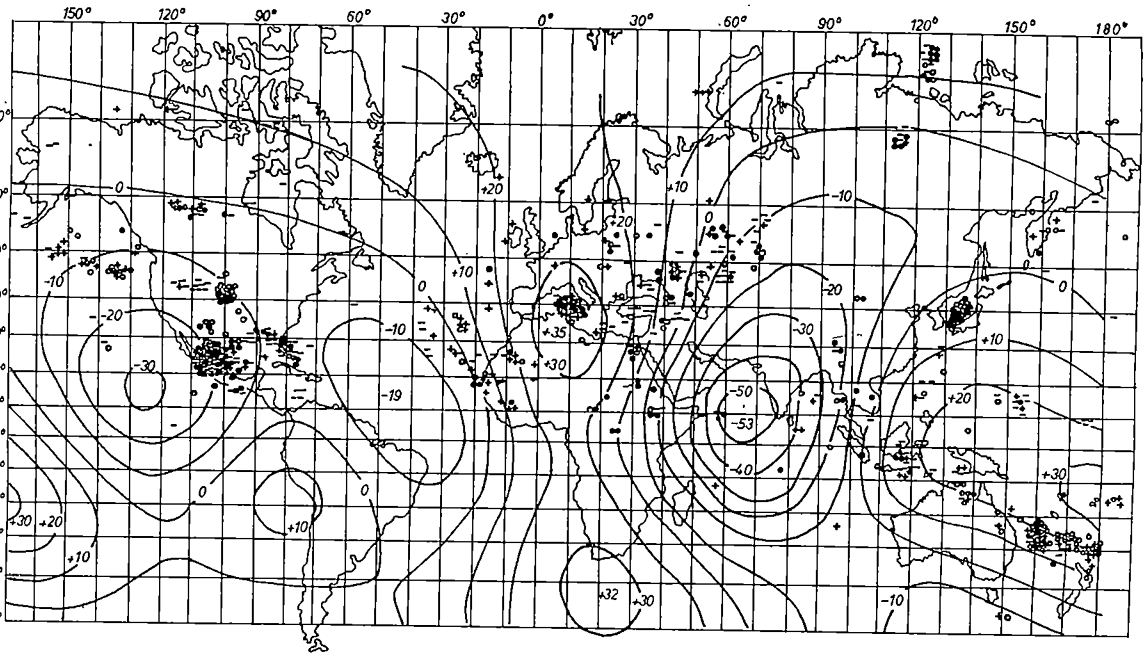

Fig. 1

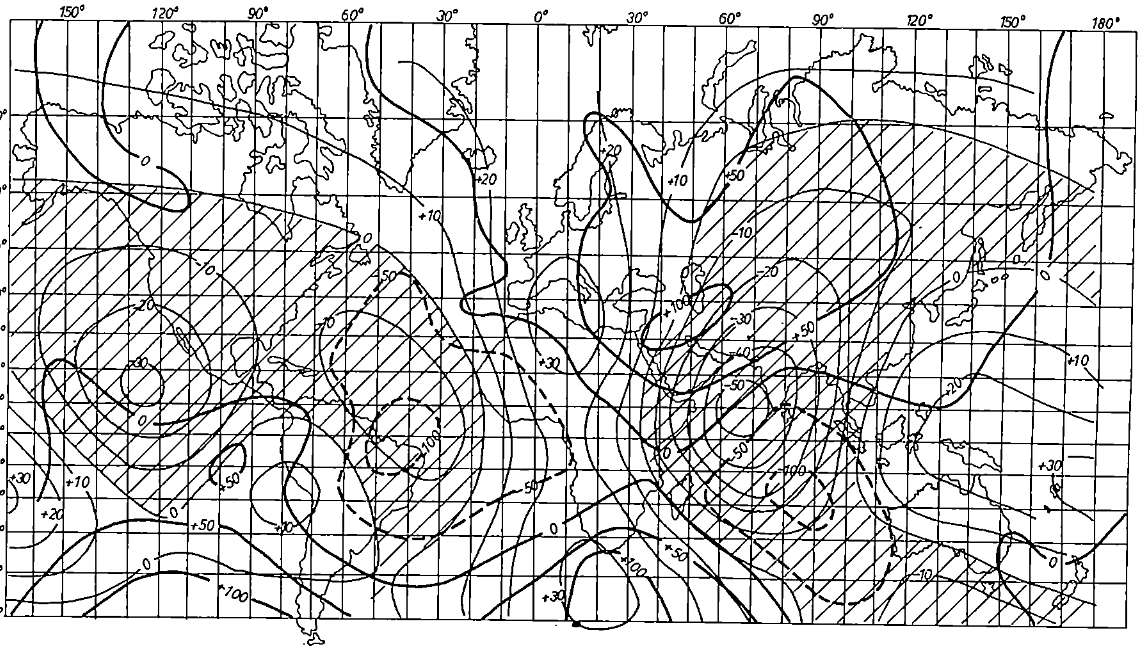

Fig. 2

a value in very good agreement with the average maximum values of geoid undulations observed.

The close connexion between geoid undulations and core undulations suggests a comparison also with geomagnetic maps.

Fig. 2 represents the isopores of vertical magnetic intensity for the year 1942·5 on the map of the satellite geoid.

There is a fair coincidence in their location, sign and trend in comparison with the undulations of the satellite geoid. It seems very probable that the coincidences of these two sets of results would be more complete by use of recent magnetic values.

If this correlation may be regarded as valid, then the gravity field must possess a secular westward drift. Moreover, the correlation points towards the importance of the core in the origin of the magnetic field. Core undulations must also show a westward drift running together with the gravity and magnetic fields, as was also suggested by Vogel[3]. The core undulations are resulting also in a variation of the momentum of inertiæ, which must be reflected in the nutational motion of the Earth, according to the formula $T_E = \frac{A}{C-A}$. The variation of the length of the Chandler nutation, between 404 and 456 days, supports this conclusion. Moreover, the close connexion between secular variation in the amplitude of nutation, geomagnetic field and angular velocity of the Earth strengthens this inference.

The high-rate core undulation and its secular variation diminish the probability of a material change at the mantle-core boundary. On the other hand, the undulations can be explained easily by the hypothesis of Ramsey, explaining the mantle-core boundary by a phase-transition of material.

A curious correlation was shown also between geoid undulations and heat-flow distribution[4], though this correlation is less tight. While the former correlations refer to deep connexions, the latter may be based only on shallow effects.

The authors[4] suggest for this correlation an explanation by convection currents. Convection currents have, however, also tectonical effects, which must be reflected in the major tectonic features of the Earth. But it is hard to discover any relation between heat-flow 'undulations' and the tectonic zones of the Earth.

I wish first of all to direct attention to the connexions between core and geoid undulations probably being the keys of problems far from being solved.

Periodic Precipitation of the Particle Flux in the Auroral Zone

EVIDENCE of periodic and quasi-periodic precipitation of the particle flux in the auroral zone is often observed in the riometer absorption[1], 5577 Å photometer records, visual observation of pulsating aurora (also seen in the all-sky camera records) and other related geophysical phenomena. Further, the recent satellite observations have also shown periodic variation in the measured flux[2]. In this communication a possible mechanism for the periodic precipitation of the particle flux is proposed and its validity and limitations are discussed.

It is well known from the work of Dessler[3], Piddington[4] and of Dessler and Parker[5] that the compressional magnetic disturbance travels along the magnetic field as a transverse hydromagnetic wave. During this period longitudinal acoustic wave propagates perpendicular to the magnetic field[6]. Herlofson[7] pointed out that in the presence of a magnetic field the longitudinal acoustic wave propagates with hybrid velocity and is known as magnetic-acoustic wave[8]. Its velocity is:

$$V_{\mathrm{ma}} = \sqrt{V_{\mathrm{a}}^2 + V_{\mathrm{hm}}^2} \tag{1}$$

where V_{ma}, V_{a} and V_{hm} are magneto-acoustic, acoustic and hydromagnetic velocities.

The incident solar plasma excites a longitudinal magneto-acoustic wave in the finite equatorial cross-section of the Van Allen belt, causing a compression and rarefaction in the intervening plasma and in the magnetic field. The magneto-acoustic waves propagating along the equatorial belt are heavily damped at high frequencies and are refracted away from the equatorial region. However, under idealized conditions such propagation at low frequencies (smaller than the proton gyro-frequency) is a possibility, and was pointed out by MacDonald[9]. The compression and the rarefaction in the magnetic field result in a one-dimensional compression and rarefaction of the intervening plasma. During compression, diffusion of the plasma along the magnetic field is comparatively more than the diffusion perpendicular to the magnetic field. Consequently, a larger number of particles will have required pitch angle ($\leqslant 2°$) to be precipitated into the auroral zone. On the other hand during the rarefaction of the magnetic field, lesser numbers of particles will have required pitch angle to be precipitated into the auroral zone. The periodicity thus produced will have the period of the magneto-acoustic wave propagating along the equatorial Van Allen belt.

The phenomena may further be complicated if there exists a coupling of the transverse hydromagnetic waves along the field lines and the longitudinal magneto-acoustic wave along the equatorial belt. The resonance between the two modes propagating perpendicular to each other will occur only when the fundamental period of one is equal to, a multiple of, or sub-multiple of the other. In this situation, particle flux heading to the lower ionosphere (having required pitch angle) is greatly affected. The period of the incident flux on the ionosphere in this case is governed by the frequency of resonance between the transverse hydromagnetic wave and longitudinal magneto-acoustic wave propagating approximately perpendicular to each other.

An approximate estimate of the fundamental period of the longitudinal magneto-acoustic wave along the equatorial belt in the presence of the magnetic field is given by:

$$T = \frac{2\pi R_E}{\sqrt{V_{\mathrm{a}}^2 + V_{\mathrm{hm}}^2}} \tag{2}$$

Taking average value of the proton mass density obtained from nose whistler data[10]:

$$\rho = 1{\cdot}2 \times 10^{-2} \frac{B_0\, e\, m_i}{2\pi e\, m_e}$$

the period

$$T = 0{\cdot}28\pi R_E^{5/2} \left(\frac{e m_i}{a\, m_e}\right)^{1/2}$$

where m_i, m_e are the proton and electron mass respectively, e is the electron charge, $R_E = 5{\cdot}4$ equatorial radial distance and $a = 8{\cdot}1 \times 10^{25}$ gauss cm^3 is the dipole moment of the Earth. The fundamental period from equation (2) becomes approximately 300 sec, which is equal to the most probable period reported by Parthasarathy and Hessler[1]. This period mainly depends on the exact knowledge of the proton mass density in the region of magneto-acoustic propagation. The periods of the transverse hydro-magnetic waves obtained from the micro-pulsations at mid-latitude[11] and from the spectral analysis of telluric currents[12] have shown the composite nature of the observed period. At higher latitude, periods anywhere between 100–500 sec having different power may exist. Under this situation there are better chances for the magneto-acoustic wave to become coupled to a suitable transverse hydromagnetic wave and give rise to a resonance effect.

The narrow latitude coverage of the observed periodicity and its simultaneous and similar appearance seen in Macquarie Island, the riometer records from which are approximately magnetically conjugate to College, is in accordance with the proposed mechanism.

I thank R. Parthasarathy and Keith B. Mather for their advice. This work was supported in part by the National Aeronautics and Space Administration Contract No. *NAS*5–3595 and U.S. National Science Foundation grant *GP*–947.

Electron Microprobe Analysis of the Metallic Phase in Basic Achondrites

There are no modern analyses in the literature of the nickel and cobalt contents of the rare metallic phase in those achondritic meteorites which have gross chemical compositions similar to terrestrial basic igneous rocks. I have called these achondrites the basic achondrites and both the eucrites and the howardites are included in this group.

The question of the composition of the metallic grains in basic achondrites has an important bearing on the evolution of these meteorites but the main problem is that their rarity and small sizes have made accurate conventional chemical analysis difficult. In the work recorded here an Applied Research Laboratories electron probe X-ray microanalyser was used to determine iron, nickel and cobalt abundances in a number of metallic grains in the Macibini eucrite and the Binda howardite. The analytical method and the standards used have been described previously[1].

Table 1. Analyses of Metallic Grains in Basic Achondrites

Meteorite	Metallic grain identification	Fe (%)	Ni (%)	Co (%)	Ni/Co
Macibini eucrite	1	97·3	2·15	0·54	4·0
	2	93·2	2·21	0·54	4·1
	3	97·3	2·00	0·64	3·1
	4	97·2	2·53	0·29	8·7
	5	95·2	3·85	0·92	4·2
Binda howardite	1	95·8	1·95	2·19	0·89
	2	98·2	0·44	1·38	0·32
	3	95·9	1·93	2·20	0·88
	4	95·8	2·00	2·18	0·92
	5	95·7	2·10	2·19	0·96
	6	95·7	2·06	2·22	0·93

The results indicate that although the nickel and cobalt contents measured at various places on individual grains seem to be constant within the precision of the method (approximately ± 3 per cent), there is considerable variability between different grains in each meteorite. In the Macibini eucrite the nickel content of various metallic grains ranged from 2·00 to 3·85 per cent and cobalt ranged from 0·29 per cent to 0·92 per cent (nickel/cobalt = 4·0–8·7). In the metallic grains in the Binda howardite, nickel ranged from 0·44 to 2·1 per cent and cobalt from 1·38 to 2·22 per cent (nickel/cobalt = 0·32 – 0·96) (Table 1). Both these meteorites show evidence of severe brecciation so that the variation observed between grains within each achondrite may well result from slight differences in the environments in which individual metallic grains were formed.

The low nickel/cobalt ratios measured in the metallic grains of the basic achondrites are quite different from the ratios observed in the metallic phase of other meteorites. For example, the average nickel/cobalt ratio in the metallic phase of the hypersthene–olivine, bronzite–olivine and enstatite chondrites is close to 20. Similarly the average nickel/cobalt ratio in the metallic phase of pallasites, which has previously been suggested to be the parent material from which the iron meteorites have evolved[2], is also 20 (Table 2).

Table 2. Composition of Metallic Phase in Meteoritic and Terrestrial Materials

Material	Fe (%)	Ni (%)	Co (%)	Ni/Co
Average metallic phase of hypersthene–olivine chondrites (ref. 3)	79·7	19·4	0·88	22·2
Average metallic phase of bronzite–olivine chondrites (ref. 3)	88·0	11·4	0·55	20·6
Average metallic phase of enstatite chondrites*	92·5	7·1	0·35	20·2
Average metallic phase of pallasites (ref. 3)	88·4	11·0	0·55	20·0
Metallic phase in Disko Island Basalt (carbon free) (ref. 1)	97·6	1·76	0·68	2·6

* Average of five superior analyses: Hvittis, Indarch, Saint Sauveur (ref. 4) and Abee (matrix), Abee (fragment) (ref. 5).

On the other hand, the metallic masses occurring in the basic igneous rocks at Uifaq, Disko Island, West Greenland, have nickel and cobalt abundances and nickel/cobalt ratios almost indistinguishable from the metallic phase in the Macibini eucrite and very similar to that in the Binda howardite (Tables 1 and 2). The metallic masses in the Disko Island rocks are generally considered to have been formed by the virtually complete reduction of oxidized nickel and cobalt, and the partial reduction of oxidized iron, in a basic silicate magma as a result of reactions with carbonaceous matter derived from surrounding coal measures or carbonaceous shales which these rocks are observed to intrude[1]. In view of the close similarity between the metallic phase in the Disko Island basalts and the basic achondrites, it is suggested that the metallic phase in the basic achondrites has formed from partial reduction of the parent basic magmas from which these achondrites have evolved.

PHYSICS

Chromium Oxide–Chromium Cermets

The preparation and properties of chromic oxide–chromium cermets have been examined as part of a general investigation into the possibility of preparing metal–ceramic mixtures ('cermets') by partial reduction of refractory oxides. The method consists of pressing a mixture of chromic oxide and carbon, both in the finely divided state, into compacts and sintering to temperatures in the range 1,400°–1,600° C in a vacuum of circa 10^{-4} mm mercury. The amount of carbon is calculated to give 1–10 per cent metallic chromium in the sintered body.

Under the foregoing conditions, considerable shrinkage of the compact occurs, resulting in an increase of density in a typical case from 3·2 to 4·7 g/cc. This can be compared with an increase in density from 3·2 to 3·4 for pure oxide sintered to the same temperatures. The increase in sintered density is accompanied by an increase in compressive strength from 3 tons/in.^{2} for the pure oxide to approximately 20 tons/in.^{2} for the cermets.

Provided that the temperature of sintering is sufficient to cause the reduction to proceed to completion, the most significant variable affecting sintered density is the proportion of carbon. Less than a threshold addition produces no effect, whereas more than the optimum causes the density and compressive strength to fall off, though less markedly. The latter deterioration is presumably due to an expansion effect of the carbon monoxide involved.

The mechanism responsible for this unusual shrinkage is being investigated.

GEOLOGY

Age of the Newgale Beds

The Newgale Beds of Pembrokeshire (Fig. 1) have not previously yielded any fossil evidence about their age, and consequently there has been considerable doubt on this matter. On the earliest map of the area[1] they are shown as Carboniferous, an interpretation that is retained on the map published by Jones[2]. On the Geological Survey Map of 1917[3] they are more specifically identified as Millstone Grit.

In recent years their Carboniferous age has been questioned and Jenkins[4] considered them, without positive evidence, to be Lower Palaeozoic. Owen, in the discussion of this paper, stated they may be either Cambrian or a facies variant of the Llandovery. Jones, in discussing the same paper, said that if they are Cambrian they most likely are equivalents of the Middle Cambrian, Solva Series.

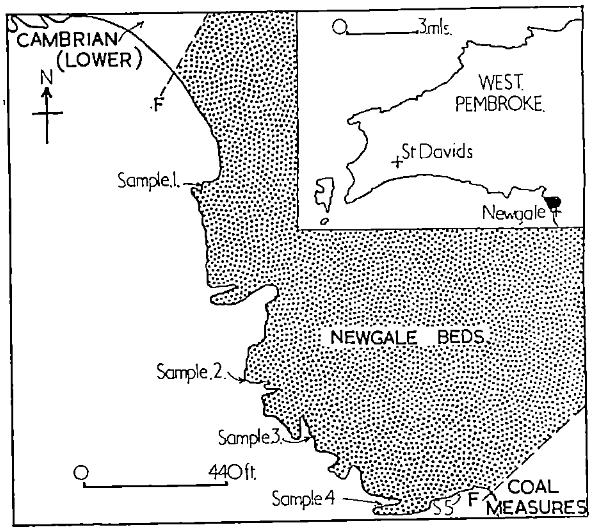

Fig. 1. Map showing the location of the Newgale Beds and the samples examined

	3	6	12	8	3	3

One of us (H. G. D.) while mapping the area collected a number of samples which were processed in the Micropalæontology Laboratory, Geology Department, University of Sheffield. The samples were selected dark grey mudstones occurring as thin bands among the sandstones and grits which form the greater part of the Newgale Beds. Five samples were treated, Nos. 3–5 yielding a large number of microfossils of the type once known as hystrichospheres but now called acritarchs[5]; the others yielded small numbers of similar types. These assemblages, typical members of which are illustrated in Fig. 2, are clearly Cambrian in age. An earlier date is eliminated by the presence of *Acanthodiacrodium* (Fig. 2*n*, *o*) and *Archaeohystrichosphaeridium* (Fig. 2*i*–*m*). An Ordovician or Silurian age can be discounted because of the absence of *Veryhachium*, *Tasmanites*, *Leiofusa*, certain species of *Baltisphaeridium*, and chitinozoa, and because of the presence of *Acanthodiacrodium*, which is typically Cambrian. The absence of spores and plant debris excludes any younger age.

Dating within the Cambrian is less certain because no systematic work has been done with fossils of this type in the British Cambrian. One of us (C. D.) has observed acritarchs in Lower and Upper Cambrian rocks of Wales and Scotland which differ in type from those discussed here, but the Middle Cambrian has not yet been investigated. In these circumstances the only comparative material is that from the Baltic regions of U.S.S.R. described by Timofeyev[6]. Counterparts of all the species found in the Newgale Beds can be found among those described by Timofeyev but none is so closely similar that specific identification is certain. In each case the Welsh species is compared with that most closely resembling it in Russia. It should be noted that no triradiate marks have been observed in any of the species from Wales. The stratigraphic range of these Russian counterparts is shown in the table, which clearly indicates a Middle Cambrian age. Complete confirmation of this must wait until detailed work on the main sequences of Cambrian rocks in Pembroke has been carried out.

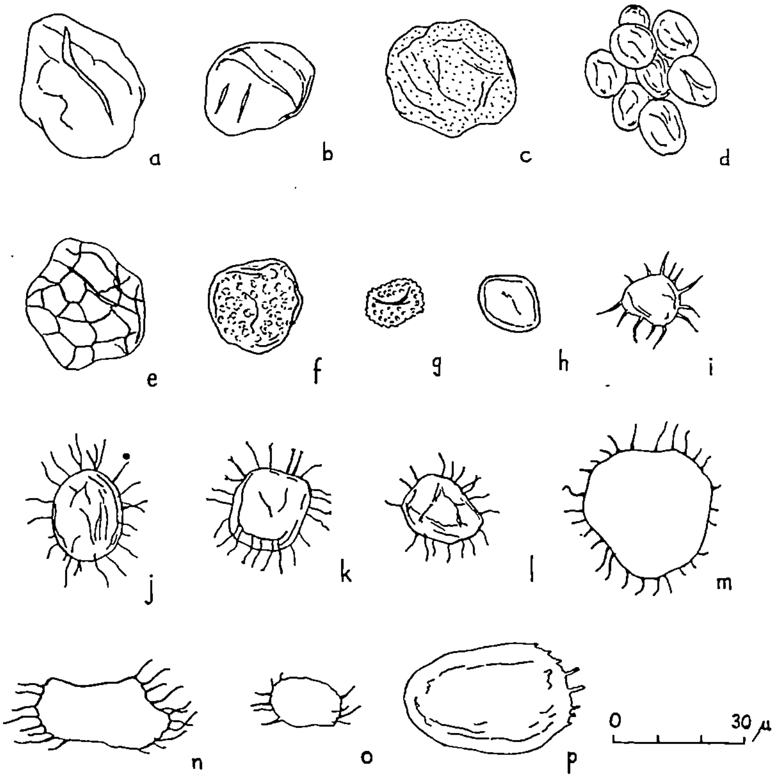

Fig. 2. Camera lucida drawings of the more common acritarchs in the Newgale Beds. *a and b*, cf. *Trachyoligotriletum minutum*; *c*, cf. *Ocridoligotriletum kryshtofovichi*; *d*, *Protoleiosphaeridium* sp. cf. *conglutinatum*; *e*, *Protoleiosphaeridium* sp.; *f*, cf. *Trachyoligotriletum rugosum*; *g*, cf. *Tyloligotriletum asperum*; *h*, cf. *Stenozonoligotriletum sokolovi*; *i*, *Archaeohystrichosphaeridium* sp. *cf. strictum*; *j* and *l*, *Archaeohystrichosphaeridium* cf. *operculatum*; *k*, *Archaeohystrichosphaeridium* cf. *minor*; *m*, *Archaeohystrichosphaeridium* cf. *oblongum*; *n*, *Acanthodiacrodium* sp. cf. *barbullatum*; *o*, *Acanthodiacrodium* sp. *cf. secundarium*; *p*, cf. *Ooidium sablincaense*

Meanwhile the palæontological evidence proves a Cambrian age and is strongly suggestive that it is Middle Cambrian. This being so the Newgale Beds, as Jones stated, must be equated with the Solva Series, the Menevian Series of the Middle Cambrian being a most improbable equivalent because of its lithology.

We thank Mr. P. Shepherd for making the preparations and Prof. L. R. Moore for the use of the facilities of the Department of Geology at Sheffield.

Coal Ranks and Geothermal Gradients in High-volatile Bituminous Coalfields

FORTY samples of coal from oil-prospecting wells drilled by Shell BP Todd Oil Services, Ltd., in the Taranaki area of New Zealand have been analysed at the Chemistry Division of the New Zealand Department of Scientific and Industrial Research. Full analytical details and a discussion of the depth/rank relation are given by us[1], and we emphasize that direct comparison of the analyses is not satisfactory because the coal types and sulphur contents vary widely. It was necessary to make some allowance for these variations, the method used being that of Suggate[2]. Within the high-volatile bituminous range of rank penetrated in the wells, the most satisfactory parameter of rank is the calorific value.

All four wells penetrated coals ranging through stratigraphic intervals of between 2,100 and 2,500 ft., the deepest coals being from depths ranging between 12,900 and 14,700 ft. The coal measures are of Upper Eocene or Lower Oligocene age[3], and above them sediments from Oligocene to early Pleistocene in age were deposited without major breaks in sedimentation. Slight uplift and erosion followed, and for some wells it has been found possible to make reasonable estimates of the thicknesses eroded, and consequently of the original depths of burial. From a composite column over the 12,000–17,000 ft. range of depth of burial, an increase of 280 B.T.U./lb. per 1,000 ft. increase of depth is estimated; individual well sequences, based on comparatively few analyses, tend to show rather lower rates of increase of calorific value with depth.

The proximate analysis (air-dried basis) of the most deeply buried coal is as follows: M., 1·2 per cent; V.M., 44·1 per cent; F.C., 48·4 per cent; A., 6·3 per cent; S., 1·2 per cent; B.T.U./lb., 14,380; Sw. No., 6½. If it is assumed that no great changes in geothermal gradient have occurred since the early Pleistocene, this coal was metamorphosed at a temperature of 280°–300° F., judged by temperature measurements in the wells.

The rate of increase of calorific value with increasing depth is only a little more than half the 500 B.T.U./lb / 1,000 ft. found in Carboniferous coals in the Pie Rough Bore in England[4] and in bores in the Saar and Upper Silesia[5]. The most obvious explanation is that of a nearly two to one difference in geothermal gradient. Comparison of data from the Carboniferous coalfields of the Netherlands with analyses of single samples of Jurassic coal from Mississippi at a depth of 16,193 ft. and of Eocene coal from Venezuela at a depth of 11,200 ft. has already led Kuyl and Patijn[6] to suggest that the geothermal gradient in the Carboniferous was much greater than in Mesozoic and Tertiary times. The present geothermal gradient in the Taranaki coal measures is about 19° F./1,000 ft., and if that in the European Carboniferous were greater in proportion to the difference between the rank gradients, it would have been about 34° F./1,000 ft. Such a high gradient, however, is greater than that now found at depth almost anywhere except in hydrothermal areas. Before this gradient is accepted for the Carboniferous, the effects of possible lower pressure should be considered[7], if depth of burial was less and the temperature gradient only moderately higher.

We thank the geologists of Shell BP Todd Oil Services, Ltd., for their assistance.

CRYSTALLOGRAPHY

Production of Dislocation Etch Pits on Calcite using Optically Active Etchants

SEVERAL etchants, usually consisting of aqueous solutions of organic acids, have been shown[1-5] to produce etch pits at the points of emergence of dislocations on the rhombohedral cleavage faces of calcite crystals. Moreover, if the pits are particularly well defined it is often possible to deduce, from their internal structure, the plane and the direction in which the dislocation line runs through the crystal, a possibility of considerable interest to us since we are endeavouring to assess the role of line imperfections in the chemical reactivity of calcite.

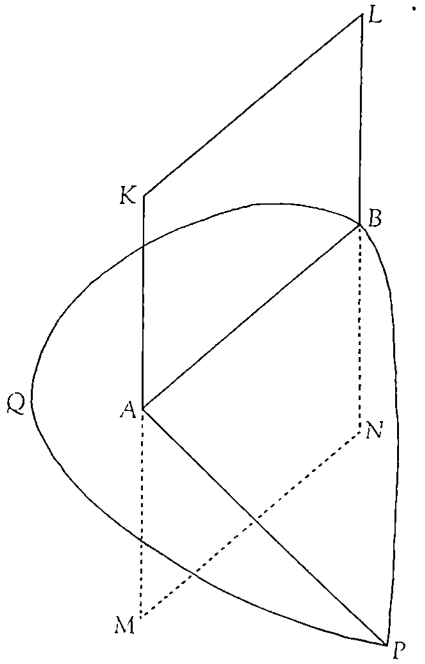

Fig. 1. Schematic representation of etch-pit produced by D- and L-tartaric acids showing plane in which the dislocations lie. Dotted lines indicate the section of the plane below the plane of the paper

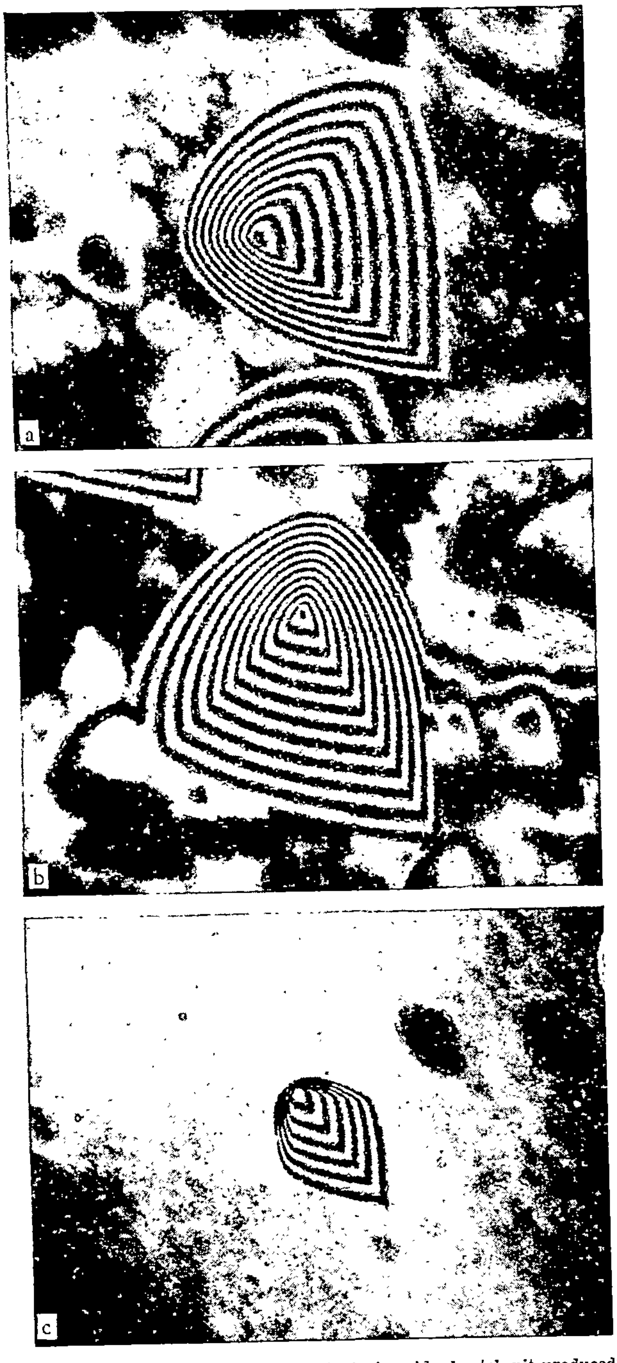

Fig. 2. *a*, Etch pit produced by D-tartaric acid; *b*, etch pit produced by L-tartaric acid; *c*, etch pit produced by *meso*-tartaric acid. Interferograms (× *c*. 425)

It has been shown by Gilman and Keith[4] that the nature of the anion of the organic acid used as etchant is important in deciding such characteristics as the orientation and internal structure of the dislocation etch pits; and since these are the characteristics which are used to arrive at the crystallographic directions of the dislocation lines, we decided to devise a simple test to ascertain whether it is possible to obtain reliable information concerning the direction of the dislocation line from the differently shaped pits produced by different etchants.

Bengus *et al.*[2] state that, for a pyramidal pit such as that shown diagrammatically in Fig. 1, *PQB*, the plane in which the dislocation line lies, is that which is constructed by taking the pit edge (*AB*) opposite the steepest face and projecting this edge on to the base of the pit. Thus, the relevant plane is *KLMN* in Fig. 1. The steepest faces of the etch pits described by Bengus and in this communication were determined using optical interference microscopy[6].

Figs. 2*a* and *b* are interference photomicrographs (sodium light illumination) of separate parts of the same 'as-cleaved' surface of a calcite rhomb, one end of which was immersed, with gentle agitation, for 60 sec in 10 per cent aqueous solution of D-tartaric acid at 22° C, and the other in L-tartaric acid under identical conditions. Immediately following etching the crystals were washed, successively, in running water, ethanol, ether and finally dried in air. In all the photomicrographs shown here the top edges of the micrographs lie along the [100] direction.

It is to be noted that a change in pit orientation for D- and L-tartaric acids occurs, and that the angle through which the pit is re-oriented is, to within experimental error, the same as the obtuse angle in calcite, 102°. This reveals that the etching process is stereospecific, a fact recorded prior to the advent of dislocation theory in the investigations of Honess and Jones[7], who found that the pits produced by the D- and L-acids were mirror images.

Micrographs such as those shown in Figs. 2*a* and *b* verify that the test of Bengus *et al.*[2] holds good because, even though marked re-orientation of the pits takes place, the plane in which the dislocations lie, determined as described here, remains unaltered when either the D- or the L-tartaric acid is used.

Quite apart from substantiating Bengus's method, this work, which is continuing, opens up the possibility that stereoisomeric etchants, such as D- and L-tartaric acids, may be able to distinguish right-handed from left-handed screw dislocations or positive from negative edge dislocations. Some caution is, however, required for we have found that, using an aqueous solution of *meso*-tartaric acid as etchant, under the conditions described above, it is extremely difficult to evaluate the plane in which the dislocation lies from the internal structure of the etch pit (Fig. 2*c*).

We thank Prof. S. Peat for his advice and the Department of Scientific and Industrial Research for a maintenance grant to one of us (C. R.).

CHEMISTRY

Nitrous Oxide as a Scavenger for Electrons in the Radiolysis of Propane

Recent investigations of the radiation chemistry of liquid hydrocarbons indicate that in these systems N_2O reacts rapidly with electrons but relatively slowly with hydrogen atoms[1]. We have investigated the effect of N_2O in the radiolysis of propane gas, and the results obtained have led to information about the mechanism of hydrogen formation.

The gas mixtures (760 mm mercury) were irradiated in 'Pyrex' vessels (~400 ml.) using a cobalt-60 γ-ray source. The dose-rate in propane was 5×10^{14} eV ml.$^{-1}$ min^{-1} (nitrous oxide dosimeter: assuming $G(N_2) = 12{\cdot}5$ molecules/100 eV[2] and using an experimentally determined value of 1·42 for the stopping power of propane relative to N_2O). Total doses were 10^{16}–10^{17} eV ml.$^{-1}$. The results, taken from linear yield-dose plots, are given in Table 1.

The yield of hydrogen from pure propane was found to be $G(H_2) = 6·5$ and was in agreement with previously reported values[3,4]. Addition of N_2O decreased the yield of hydrogen and led to the formation of nitrogen. The yields of H_2 and of N_2 were independent of the N_2O concentration between 2 and 4 mole per cent.

In propane, containing N_2O and propylene at equal concentrations ($\sim$ 3 mole per cent), the yield of N_2 was the same as in the absence of propylene. It is known[5,6] that the ratio of the rate constants $k_{(H+C_3H_6)}/k_{(H+N_2O)} \gg 10^5$, and it may be concluded that hydrogen atoms will react exclusively with propylene under these conditions. The formation of N_2, therefore, cannot be due to the reaction of hydrogen atoms with N_2O.

Table 1. RADIOLYSIS OF PROPANE (760 MM MERCURY, 20° C). EFFECT OF ADDED N_2O, SF_6, CCl_4 AND PROPYLENE

Additive	Yield (molecules/100 eV) Hydrogen	Yield (molecules/100 eV) Nitrogen
None	6·5	—
N_2O (2–4 mole %)	4·2	7·5
C_3H_6 (3 mole %)	1·75	—
C_3H_6 (3 mole %) + N_2O (3 mole %)	1·75	7·5
SF_6 (5×10^{-3} to 3 mole %) + N_2O (3 mole %)	4·2	0
CCl_4 (3 mole %) + N_2O (3 mole %)	4·2	0

Our results can be interpreted by assuming that, in irradiated propane + N_2O mixtures, N_2 is formed by reaction of electrons with N_2O, an assumption which would be consistent with the reactions of N_2O in irradiated liquid systems[1,5,7,8]. In electron beam experiments it has in fact been shown that the capture process:

$$e^- + N_2O \rightarrow N_2 + O^- \qquad (1)$$

can occur with electrons of thermal energies[9].

On the basis of this interpretation, SF_6 and CCl_4, which have large cross-sections for electron capture[10], should be able to compete with N_2O for electrons. We have found that this is the case and that the cross section for electron capture by SF_6 is at least 10^4 times as great as that of N_2O.

Since the energy for the formation of an ion pair in propane is 26·3 eV[11], the yield of electrons $G_e = 3·8$. The value of $G(N_2) = 7·5$ obtained in our experiments suggests that electron capture by N_2O in the gas-phase leads to the production of two molecules of N_2. It is possible that, under these conditions, reaction (1) is followed by:

$$O^- + N_2O \rightarrow N_2 + O_2^-$$

which would be at least 3 eV exothermic.

The decrease in $G(H_2)$ when an electron scavenger (N_2O, SF_6, CCl_4) is added to propane may be attributed to a change in the process by which the positive ions are neutralized. In the absence of an electron scavenger, the ion will be neutralized by an electron; with an electron scavenger present, however, the neutralization will involve a negative ion. If it is assumed that neutralization by negative ions does not lead to hydrogen formation, then the decrease in $G(H_2)$ of 2·3 found on adding N_2O, SF_6, or CCl_4 corresponds to the hydrogen yield resulting from electron-ion neutralization in pure propane. This value is less than G_e, suggesting that only approximately 61 per cent of the neutralization events in propane lead to formation of H_2.

The decrease in the hydrogen yield to $G(H_2) = 1·75$ when propylene is present has been observed previously and is attributable to the scavenging of hydrogen atoms by the olefin[3]. The hydrogen yield in the presence of propylene is not influenced by N_2O. It would appear, therefore, that this 'molecular' H_2 is not produced as a result of ion neutralization, a finding that is in agreement with evidence discussed previously by Back[3].

We thank Prof. J. J. Weiss for his advice and Dr. G. Scholes and Dr. M. Simic for helpful discussions.

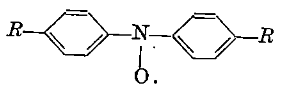
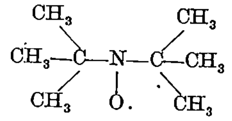
Stable Nitroxide Radicals

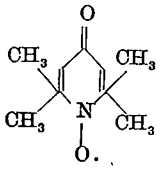
THE stability of organic free radicals is generally attributed to electron delocalization, steric inhibition of dimerization, or both (for example, 2,4,6-tri-*t*-butylphenoxyl), and the nitroxide radicals appear to accord well with these views. In the well-known diaryl nitroxides (I)[1,2] the >N—O group is attached to two conjugated systems, in (II)[3] and (III)[4] and related radicals[5] it is highly hindered, while in (IV)[6] and (V)[7] both conjugative and steric factors may contribute to radical stabilization.



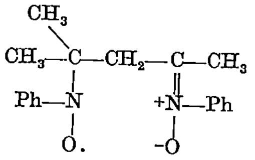
(I)



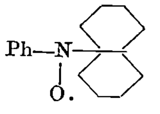
(II)



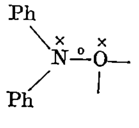
(III)



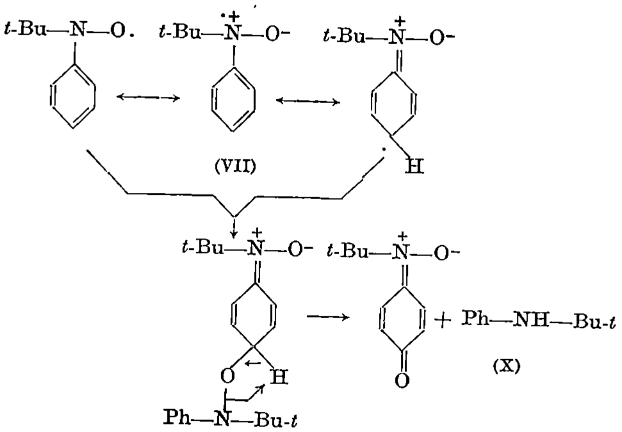
(IV)



(V)



(VI)



(VII)

(VIII) (IX) (X)

According to Linnett[8], however, the stability of nitric oxide and the organic nitroxides can be explained by the double quartet hypothesis; on this basis diphenyl nitroxide (VI) (Linnett's notation) is resistant to dimerization because the total number of electrons involved in bonding would not thereby increase, whereas electron repulsion would. Conjugative and other factors are disregarded.

t-Butyl phenyl nitroxide (VII)[9-10], which we have prepared by oxidation of the corresponding hydroxylamine (from *t*-nitrosobutane and phenyl magnesium bromide) with silver oxide, undergoes continuous decomposition in air over a period of several days to form *t*-butylaniline (X) and N-*t*-butyl-*p*-benzoquinonimine N-oxide (IX). The production of these compounds can be accounted for by the coupling of the radical at the *para* position of the benzene ring as shown. Diphenyl nitroxide (I; $R = \text{H}$) decomposes similarly in ether solution to diphenylamine and N-phenyl-*p*-benzoquinonimine N-oxide[2]. This mechanism is analogous to that proposed for the oxidation of phenols to quinones by the nitroxide, Fremy's salt[11].

It appears, therefore, that the relatively low stability of diphenyl- and *t*-butyl phenyl nitroxides can be attributed, at least in part, to their tendency to dimerize to unstable adducts of the type (VIII), which rapidly decompose. These results, together with the observed hyperfine structure of the electron spin resonance spectra of (I)[12] and (VII)[9] and related radicals[13], and the fact that the dianisyl (I; $R = \text{OCH}_3$)[14,15] and the 4,4′-dinitrodiphenyl (I; $R = \text{NO}_2$) nitroxides are much more stable than the parent radical (I; $R = \text{H}$), show that the odd electron is not confined to the $>$N–O bond in these radicals.

We are investigating the possible use of stable nitroxide radicals as replacements for Fremy's salt in oxidation reactions; in general we find that they will abstract hydrogen from N—H and S—H bonds but they do not oxidize monohydric phenols to quinones.

Note added in proof. Since this communication was submitted the preparation of the hydroxylamine and the nitroxide has been reported by A. K. Hoffmann, A. M. Feldman and E. Gelblum, *J. Amer. Chem. Soc.*, 86, 646 (1964).

Redox Cleavage of S—S Linkage in Diaryl and Cyclic Alkyl Disulphides

THE rupture of S—S linkages in organic disulphides by either ionic or free radical processes is well known. On the other hand, redox cleavage of such S—S bonds has never been demonstrated, although Kolthoff[1] postulated that ferrous citrate complex with organic disulphide underwent redox transformation analogous to that with hydrogen peroxide. However, this observation was made under quite different conditions in their polarographic investigations.

I wish to report that diaryl disulphides, such as phenyl disulphide, and cyclic disulphides, such as 1,2-dithiolane-3-valeric acid (lipoic acid), interact with organometallics such as ferrocene and vanadium acetylacetonate to yield the corresponding thiyl radicals, mercaptide ions and the concomitantly oxidized metal ions. In a typical run. 10 mg (0·05 mmole) of phenyl disulphide (Eastman. m.p. 59°–60°) and 4 mg (0·02 mmole) of ferrocene (Aldrich Chem. Co., m.p. 174°–176°) in 10 g (70 mmole) of purified *n*-butyl methacrylate at room temperature in the dark produced 150 mg of polymers over a period of 20 h, while phenyl disulphide or ferrocene alone in the same monomer failed to yield any polymer under the same conditions. The oxidation of ferrocene is evidenced by the appearance of the faint blue colour of ferrocenium ion. When the reaction was carried out in ethanol instead of vinyl monomers with an appreciably higher concentration (2 mmole of each of phenyl disulphide and ferrocene in 100 ml. of ethanol) under the same conditions as in the previous experiment, the reaction mixture furnished a few per cent of lead mercaptide, after treating the mixture with lead acetate, and much of the unchanged disulphide and ferrocene. It was also noticed that ferrocenium ion can be reduced by phenyl mercaptide ion, hence this reaction is a truly reversible one. The same result was obtained with lipoic acid and vanadium acetylacetonate. However, alkyl disulphides, such as benzyl disulphide, butyl disulphide and heptyl disulphide, failed to react with either ferrocene and acetylacetonate. It is possible that these disulphides may be responsive to other specific reductants.

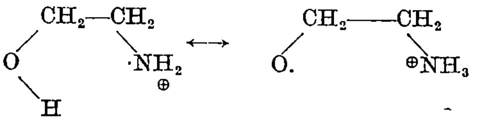
In addition to the metal induced redox cleavage of S—S bond in aryl and cyclic alkyl disulphides, we also have noticed that certain basic nitrogen compounds, such as *N*,*N*-dimethylaniline, trialkylamines, ethanolamine and substituted pyridines are also effective in cleaving the same kind of disulphide linkages, as evidenced by initiation of polymerization of acrylonitrile. For example, a solution of 50 mg (0·25 mmole) of phenyl disulphide and 60 mg (0·5 mmole) of *N*,*N*-dimethylaniline in 10 g (190 mmole) of acrylonitrile in the dark at room temperature became completely solidified within 5 h. Other reactive but less-effective amines are triethylamine, tributylamine, 2,4,6-trimethylpyridine and ethanolamine; while aniline, pyridine, hydrazobenzene and tribenzylamine failed to react with phenyl disulphide. In the case of lipoic acid, the same result was obtained with *N*,*N*-dimethylaniline, ethanolamine, 3-hydroxypropylamine and 2-amino-2-methyl-1,3-propandiol, while other amines were not effective.

Ionic scission of sulphur–sulphur bonds on attack of nucleophilic reagents is known[2-4], but the disulphides reported capable of interacting with ammonia and amines are limited to only 2-benzothiazyl disulphide[5] and ethyl xanthic acid disulphide[6]. Since ionic scission of S–S bonds by amines appears to be limited to a few specific disulphides, I propose that the series of reactions between diaryl and cyclic disulphides with various amines examined in our laboratory proceeds by a redox free radical mechanism.

The amine and disulphide reaction may parallel to the known free radical process exhibited by certain organic peroxides and amines[7-9], wherein an ionic intermediate formation was suggested to be the rate-controlling step. However, I have observed no correlation between the basicity of nitrogen compounds and their activity toward cleavage of the sulphur–sulphur linkage in lipoic acid. It might be possible that in the redox cleavage of disulphide linkage with organic base, two concurrent reactions are taking place, one following the ionic intermediate route

$$R_3\text{N}{:} + R'\text{SS}R' \longrightarrow [R_3\text{N–S}R']^+ + R'\text{S}^-$$

and the other involving electron transfer process as demonstrated in the disulphide–organometallic interaction. The former mechanism is preferred in the case of diaryl disulphides, since reactivity toward these parallels the basicity of the bases, whereas the latter mechanism is preferred in the case of lipoic acid since reactivity toward this molecule is apparently exhibited only by bases which can form stabilized cationic radicals. Of course, it is also possible that the low reactivity of stronger bases, such as triethylamine, in this case may be attributed to salt formation with the lipoic acid. The reactivity of ethanolamine in cleaving S—S bond in lipoic acid is an interesting case. We may speculate that the amine cationic radical resulting from a direct electron transfer mechanism can be stabilized by tautomerism between the following forms:



In line with this hypothesis, I found 1-amino-3-propanol to be equally effective. In this case the geometry of the molecule still permits such tautomeric transformation, while other amino alcohols showed no effect.

The redox cleavage of disulphides with basic organic molecules and organometallics may have implications in certain biological systems.

I thank my colleagues at Arthur D. Little, Inc., for their advice and the research committee of Arthur D. Little, Inc., for its support.

Role of Grinding of Titanium Trichloride in Natta's Polymerization

THE kinetic behaviour in the initial stages of the polymerization of propylene with titanium trichloride–triethyl aluminium can be divided into two types: the build-up type (the rate increases to the stationary value) and the decay type (the rate approaches decreasingly to the value). Natta and Pasquon[1] observed that the build-up type changed into the other type as grinding the titanium trichloride, whereas the stationary rate did not change, and supposed that the produced polymer adjusted the particle size of titanium trichloride into the stationary value appropriate for the stationary polymerization. This supposition is based on the experimental result that the same stationary rate per unit weight of titanium trichloride was obtained with the use of the titanium trichloride catalysts in various particle sizes.

We have carried out the polymerization with the titanium trichloride catalysts ground in various degrees and confirmed the change in the types of the rate-time curve, excepting the different values of the stationary rate, as follows.

The titanium trichloride was obtained from Stauffer Co., Ltd. (prepared from titanium tetrachloride by reduction with hydrogen), of which the surface area is 3·5 m²/g. Grinding the titanium trichloride with a small ball mill in nitrogen atmosphere 30–100 h, we have the ground catalysts. Using the BET method with nitrogen adsorption, the surface areas of the ground catalysts have been determined as shown in Table 1.

Table 1. GRINDING TIME AND SURFACE AREA

Hour	0	36	50	70	100
m²/g	3·5	10·3	18·9	22·1	24·1

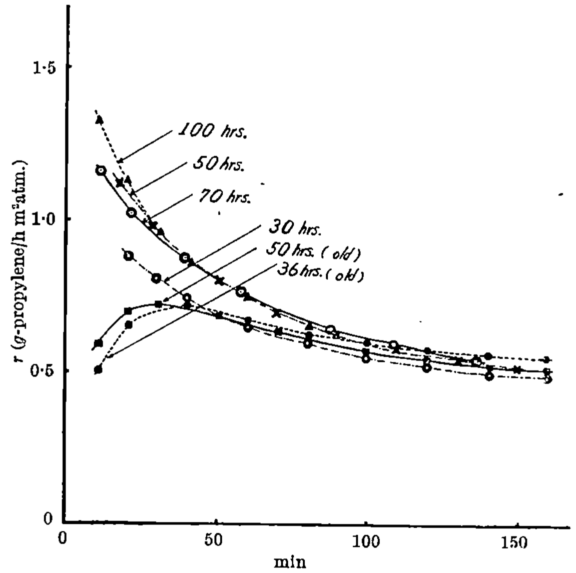

Fig. 1. Polymerization rate and time

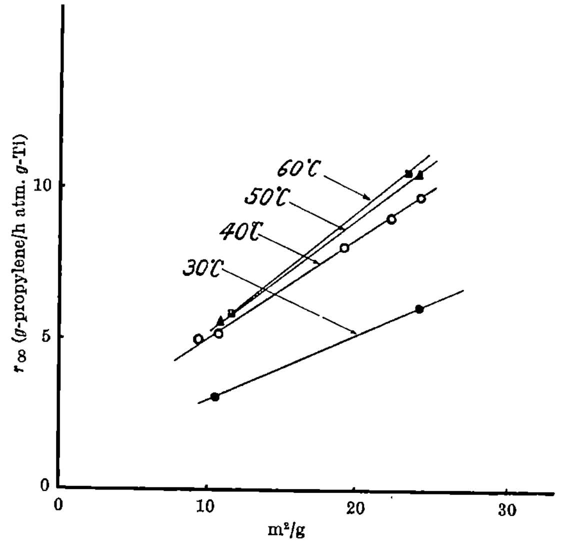

Fig. 2. Stationary rate and surface area

Carrying out the polymerization with these catalysts under the condition that aluminium/titanium 1, n-heptane 250 ml. and 30°–60° C, the rate-time curves have been obtained as illustrated in Fig. 1, where the rate is expressed by g propylene/h atm m². The decay type of the curve can be represented by the following equation[2]:

$$r = B \exp(-kt) + r_\infty$$

with $$r_\infty = A \exp(-10\,\text{kcal}/RT)\,P$$

where t is the polymerization time, P the pressure of propylene and B, k, A are the constants. Applying the equation for the experimental data, we have the calculated value of r_∞ which corresponds to the stationary rate. The calculated value per unit weight of the catalyst is approximately proportional to the surface area as shown in Fig. 2.

From these results we have arrived at the conclusion that the stationary rate is proportional to the surface area of the catalysts used and the effect of the grinding may be divided into two effects: the expansion of the surface area and the promotion of the initial activity. The decay type obtained with the ground catalysts changed to the build-up type with the same catalysts maintained for about a month in an atmosphere of nitrogen, which shows the initial activity made to appear by the grinding is unstable.

Some Interferometric Observations on the Water/Solids Relation of Activated Sludge Flocs, using a Compression Technique

As part of a fundamental investigation of the water/solids relation of activated sewage sludge an attempt was made to apply interference microscopy[1] to the measurement of the solids content of the sludge floc.

The gelatinous consistency and irregular shape and size of the zooglœal flocs have so far prevented any reliable estimate of the solids content of the flocs; such knowledge is of importance when investigating the behaviour of different sludges and may have a practical value in treatment plant design.

Since the calculations involved in the interferometric method required precise measurement of the thickness of the particles it was thought desirable to introduce some uniformity to the particles by compression. A cell compressor for the measurement of mass and concentration by interference microscopy has been described by Goldacre *et al.*[2]. We have found it more convenient to modify a Rousselets compressor to provide a compressed field by making a sandwich of the particles between two rubber cushioned cover-slips. For the type of material being examined this compressor has been found to be quite adequate, there being a relatively large area of compression. The compressor is also suitable for immersion refractometry.

The glass disk is removed from the base of the Rousselets compressor and the cover-slip and its retaining clips removed from the upper plate. Two small strips of rubber are cemented to the bottom of the upper plate on either side of the aperture and a strip of cover-slip 7 mm wide is placed across the aperture and cemented to the strips of rubber. The hole in the base plate is enlarged and four strips of rubber are cemented to form a square about the hole.

A drop of suspension to be examined is placed on a hæmacytometer cover-slip supported by the strips of rubber on the base plate and the upper plate racked down. Initially the cover-slips are held together by the fluid between them. Further careful racking down of the upper plate results in the formation of the sandwich between the rubber cushions on the upper and lower plates.

The thickness of the compressed field can be found by conventional focusing methods making allowance for any slight variation across the width of the cover-slip.

Alternatively the thickness of the particle may be found by using the interferometric air-bubble technique[3] or by calculating thickness from phase changes in immersion media of different refractive indices[1].

Particles can be kept under observation during the compression process and they can usually be seen to flatten and spread out. The microscope adjustment is checked and adjusted when compression is complete.

Measurements are taken using a Baker half-shade eyepiece, and monochromatic light of 5420 Å from a Didymium and Green filter.

In calculating the results a value of 0·0018 has been assumed for α as the particles contain a large amount of protein.

The results obtained for three samples of activated sludge taken from a sewage works at different times are given in Table 1.

Table 1

Sample No.	(1)	(2)	(3)
Mean concentration of solids (g/100 ml. floc.)	12·02	14·65	9·65
Mean concentration of water (g/100 ml. floc.)	90·99	89·01	92·76
Mean density	1·030	1·036	1·024

Unlike most cytological materials, activated sludge cannot be represented in terms of a typical structure and average particles dimensions, consequently it is not an easy material to examine. So far as is known this is the first time information about the *in situ* density and solids content of sludge floc has been presented.

Part of this investigation was supported by a research grant from Simon Carves, Ltd., Cheadle Heath, Stockport, Cheshire.

BIOCHEMISTRY

α-Glycerolphosphate Production by Rat Hepatomas

IT has been reported previously[1] that the α-glycerolphosphate dehydrogenase (L-glycerol-3-phosphate: NAD^+ oxido-reductase, E.C. 1.1.1.8), either the crystalline form of the enzyme (Boehringer, U.S.) or that present in the post-mitochondrial fraction of rat liver and hepatomas, could be activated by potassium cyanide. At that time it was also found, although published only recently[2], that potassium cyanide increased the anaerobic production of α-glycerolphosphate (GP) from glucose-6-phosphate by the fortified post-mitochondrial fraction of three rat hepatomas.

Pette and Ruge[3] have very recently demonstrated that potassium cyanide causes the dismutation of methylglyoxal, which contaminates the triosephosphate esters used as substrate in the enzyme assay, to pyruvate, which is then reduced by added $NADH_2$ and the lactic dehydrogenase present in the post-mitochondrial fraction. These authors also obtained evidence for a non-enzymatic oxidation of $NADH_2$ in mixtures of the triosephosphate esters, ethylenediamine tetraacetic acid and potassium cyanide.

Experiments carried out shortly after our first report[1] was made cast doubt on the identity of the potassium cyanide effects obtained with the crystalline and post-mitochondrial enzymes. Both the activity of the crystalline enzyme and the effect of potassium cyanide thereupon varied, the two being inversely related; stimulation by potassium cyanide (5×10^{-4} M) ranged from 30 to 200 per cent. In the latter cases the $NADH_2$ oxidation by the crystalline enzyme was stimulated by EDTA (10^{-3} M) < cysteamine (10 μmoles) = potassium cyanide = cysteamine plus potassium cyanide < serum albumin (0·1 per cent) = hæmoglobin (250 μg) = these proteins plus potassium cyanide. Using the post-mitochondrial liver fraction as enzyme source, cysteamine, EDTA and protein showed only a small effect (20–30 per cent increase of activity). However, the marked stimulation[1] obtained with potassium cyanide and the post-mitochondrial liver and hepatoma enzymes was abolished by addition of cysteamine (even 0·5 μmole was effective). Another difference was apparent in the presence of *p*-chloromercuribenzoate (PCMB, 5×10^{-5} and 10^{-4} M). The activity of the crystalline enzyme both in the absence and presence of potassium cyanide was reduced to zero shortly after addition of PCMB. The activities of the post-mitochondrial liver and *B Y* 484 hepatoma enzymes in the absence of potassium cyanide were likewise affected by PCMB, but the potassium cyanide-mediated increase in $NADH_2$ oxidation remained largely unaffected in these cases. Oleic acid (5 μg) inhibited the crystalline enzyme, the inhibition being reversed equally well by potassium cyanide, cysteamine or EDTA. The diminished activity of aged enzyme (300-fold dilution in water allowed to stand for some hours) could be restored with either potassium cyanide or cysteamine. When, instead of the triosephosphate esters, fructose diphosphate plus aldolase was used as substrate for the crystalline enzyme, potassium cyanide caused also an increase (30–50 per cent) in the rate of $NADH_2$ oxidation.

In view of the findings of Pette and Ruge[3] we have repeated very recently some of our experiments. Now, using the crystalline enzyme, no potassium cyanide effect could be observed. However, after addition of lactic dehydrogenase, potassium cyanide did stimulate the rate of $NADH_2$ oxidation using the triosephosphate esters, but no such effect was obtained using fructose diphosphate plus aldolase. The non-enzymatic oxidation[3] of $NADH_2$ in the presence of potassium cyanide did not operate under our assay conditions unless the concentration[1] of the triosephosphate esters was increased 3-fold. The sensitivity of the α-glycerolphosphate dehydrogenase for heavy metal ions is well known[1], and the foregoing results lead us to the conclusion that the potassium cyanide effect observed in our previous experiments with the crystalline enzyme must have been due to the presence of some sort of heavy metal ions inhibitory to the enzyme and removed by potassium cyanide. (Oleic acid may have been inhibitory by introducing such ions.) However, we agree with Pette and Ruge[3] that the potassium cyanide-mediated increase of the $NADH_2$ oxidation by the post-mitochondrial enzymes, as reported in our original paper[1], is largely due to the above-mentioned side-reaction.

Table 1. α-GLYCEROLPHOSPHATE PRODUCTION FROM GLUCOSE-6-PHOSPHATE BY LIVER AND HEPATOMA POST-MITOCHONDRIAL FRACTIONS

Tissue	mμmoles GP/mg protein/30 min KF absent	KF present
Liver (2)	222 ± 30	425 ± 67
Primary hepatomas (2)	468 ± 63	828 ± 31
Hepatoma *BY* 252 (2)	107 ± 26	285 ± 55
Hepatoma *BY* 448 (2)	170 ± 30	342 ± 39
Hepatoma *BY* 484 (5)	453 ± 51	862 ± 91

Conditions as described previously (ref. 2). The enzymatic measurement of GP was carried out according to the method of Bublitz and Kennedy (ref. 4), the results of which were found in agreement with those obtained by the method of Ciaccio (ref. 5). GP added directly to the enzyme assay mixture or to the post-mitochondrial fraction, before (not incubated) or after incubation with glucose-6-phosphate, was recovered quantitatively. Lactic acid did not affect the assay

Also in contrast to our previous report[2], the stimulatory effect of potassium cyanide on the anaerobic production of GP by the hepatoma fractions could not be confirmed in our recent experiments. Now the incubation of the fractions in the absence of potassium cyanide led to the same high amounts of GP (Table 1) as previously obtained in the presence of potassium cyanide; as before, fluoride (10^{-2} M) increased GP production. In these experiments GP was measured enzymatically[2] with the α-glycerolphosphate dehydrogenase operating in the reverse direction of that in the above experiments. It was found that added GP could not be recovered in terms of $NADH_2$ at enzyme concentrations lower than 0·1 unit/flask, unless potassium cyanide (5×10^{-4} M) or EDTA (10^{-2} M) was also added. It is suggested that the difference between our recent and previous results on GP production may also have been due to the presence of heavy metal contamination under the previous experimental conditions. If the production of GP by the post-mitochondrial fractions (Table 1) is compared with the GP dehydrogenase activities, a correlation is found in the case of the transplanted hepatomas, but not in that of liver. In the absence of potassium cyanide the specific activities of the *B Y* 252 and *B Y* 448 enzymes amounted to 30–70 mμmoles $NADH_2$ oxidized/mg protein/min. Those of hepatoma *B Y* 448 and liver amounted to 140–200 and 200–400 mμmoles $NADH_2$ oxidized, respectively. The much lower or zero activities of the hepatoma enzymes, which may also be found[1], could, in some of our experiments, be increased to the former activities by addition of cysteamine or EDTA.

In summary, our results show that rat hepatomas may contain the soluble NAD-linked α-glycerolphosphate dehydrogenase and that these tumours produce appreciable quantities of GP from glycolytic intermediates. These results are contrary to those obtained by Boxer *et al.*[6–8]. It should, however, be noted that, using the Ehrlich-Lettré ascites tumour, Boxer *et al.* were unable to demonstrate GP production, whereas Wenner and Cereijo-Santalo[9] have been successful.

Low Molecular Weight γ-Globulins of Urine and Plasma and their Relation to 7S γ_2-Globulin

IN the work recorded here, 1–3*S* γ-globulins from human urine[1], human plasma 3*S* γ-globulins[2], human plasma 7*S* γ_2-globulin and the *S* and *F* fragments obtained by papain hydrolysis of the 7*S* γ_2-globulin[3] were compared immunochemically and by means of peptide patterns.

Human 7*S* γ_2-globulin (lot No. 330–2, Squibb) was dissolved in 0·1 M potassium chloride containing 0·01 M cysteine and 0·002 M ethylenediamine tetraacetate and hydrolysed with twice crystallized papain at *p*H 7·0 in an enzyme to globulin ratio of 1 : 1,000 by weight for 30 min in a *p*H-stat at 37° C[4]. The papain hydrolysate was resolved into three protein peaks, I, II and III, by DEAE-cellulose chromatography using gradient elution from 0·01 M phosphate to 1·0 M phosphate concentration at *p*H 7·6. Protein peak I was further resolved into two peaks I–1 and I–2 by stepwise DEAE-cellulose chromatography at *p*H 7·6, first using 0·01 M phosphate and then 1·0 M phosphate; with columns of 'Sephadex *G*–100' (Pharmacia, Uppsala, Sweden), the *S* fragment in I–1 was separated from a protein that appeared to be relatively undigested 7*S* γ_2-globulin. Peak II was rechromatographed in DEAE-cellulose columns by stepwise elution at *p*H 7·6, first with 0·01 M phosphate and then with 1·0 M phosphate: two components were obtained, II–1 and II–2. Using columns of 'Sephadex *G*–100', another *S* fragment (*S*′) and the *F* polypeptide fragment were isolated from a pool of I–2 and II–2. As previously reported[5], a crystalline polypeptide fragment appeared during dialysis of the original 7*S* γ_2-globulin hydrolysate at *p*H 5·5; using 'Sephadex *G*–100', the crystalline polypeptide was separated into two components: an *F* fragment and a smaller amount of the *S*′ fragment.

1–3*S* γ-globulins were isolated from pooled human urine by pervaporation and lyophilization of the urine and chromatography through columns of DEAE-cellulose using 0·0175 M phosphate at *p*H 6·3 for elution; the first protein peak was then separated into 4 protein peaks using 'Sephadex *G*–100': the 1–3*S* urine γ-globulins were isolated in the third peak. A crude preparation of human 3*S* plasma γ-globulins was obtained from pooled Cohn Fraction VI as described by Takahashi and Schmid[2]: filtration of this preparation through a column of 'Sephadex *G*–75' layered over 'Sephadex *G*–100' yielded five protein peaks and the second peak contained purified 3*S* plasma γ-globulins. The sedimentation coefficients of the low molecular weight urine and plasma γ-globulins were verified by analytical ultracentrifugation. Since the γ-globulins used in this study were from pooled plasma or pooled urine, all of the preparations contained myeloma type I and type II antigenic determinants as revealed with specific rabbit antisera.

Electrophoresis of the different γ-globulins and polypeptide fragments on paper and in acrylamide gel is shown in Fig. 1; it will be noted that the mobilities of the different γ-globulins differed one from the other and that the human plasma 3*S* γ-globulins could be resolved into 2 proteins of different mobilities by paper electrophoresis. Two-dimensional agar diffusion with rabbit antisera specific for 7*S* γ_2-globulin revealed that the 1–3*S* urine and 3*S* plasma γ-globulins had antigenic sites similar to, but not identical with, those of *S* fragment and 7*S* γ_2-globulin (Fig. 2*A*). No antigenic similarity was demonstrated between the *F* polypeptide from 7*S* γ_2-globulin and the low molecular weight plasma and urine γ-globulins. It will be noted that the anti-7*S* γ_2-globulin antisera revealed several low molecular weight urine γ-globulins, which was also recently reported by Takatsuki and Osserman[6]. Rabbit antiserum against urine γ-globulins revealed the presence of four γ-globulins in the 1–3*S* urine γ-globulins as well as an antigenic constituent which was immunochemically unrelated to the γ-globulins of either urine or plasma; adsorption of this antiserum with serum from a child with agammaglobulinæmia removed all of the antibodies against this unrelated component but not those antibodies against the remaining 1–3*S* urine γ-globulins (Fig. 2*C*). With this anti-urine γ-globulin antiserum, there was antigenic identity between one of the 1–3*S* urine γ-globulins and the 3*S* plasma γ-globulins (Fig. 2*B*), and confirmation was obtained of the similarity but non-identity between the low molecular weight γ-globulins, 7*S* γ_2-globulin and the *S* fragment. Urine myeloma γ-globulin has been found[7] to consist of *L* chains, and the *L* chains of all the γ-globulins have been reported to be the same[7]; however, it will be noted from Fig. 2*B* that low molecular weight normal urine γ-globulins have antigenic determinants not present in myeloma urine γ-globulin. With this same antiserum, the antigenic determinants of the plasma 3*S* γ-globulins were the same as those in myeloma urine γ-globulin.

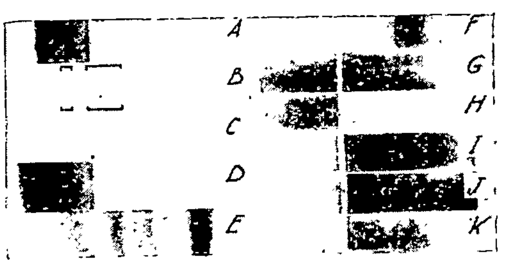

Fig. 1. *A–E*, Electrophoresis in barbital, *p*H 8·6, on paper; *F–K*, electrophoresis in glycine-*tris*-HCl, *p*H 8·3, in acrylamide gel; *A*, 7*S* γ_2-globulin; *B*, 3*S* plasma γ-globulins; bars demarcate zones of the two 3*S* γ-globulins; *C*, urine 1–3*S* γ-globulins; *D*, *S* fragment; *E*, normal serum; *F*, *F* fragment from crystallized component; *G*, papain hydrolysate of 7*S* γ_2-globulin; *H*, *S* fragment; *I*, urine 1–3*S* γ-globulins; six bands could be discerned; *J*, crude plasma 3*S* γ-globulin; *K*, fraction II-2 containing *F* fragment and *S'* fragment. Anode to the right of figure

Symbols: *U*, 1–3*S* urine γ-globulins; *P*, plasma 3*S* γ-globulins; 7, 7*S* γ_2-globulins; *S*, *S* fragment; *M*, myeloma urine γ-globulin

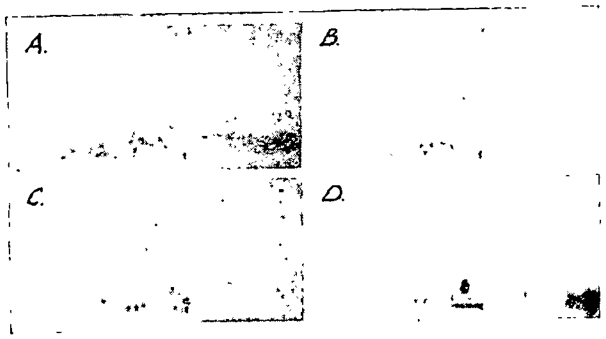

Fig. 3. Peptide patterns of trypsin hydrolysates of 7*S* γ_2-globulin (*A*), *S* fragment (*B*), 1–3*S* urine γ-globulins (*C*), and 3*S* plasma γ-globulins (*D*)

In Fig. 3, the ninhydrin stained peptide patterns of trypsin hydrolysates of the different γ-globulins are compared: these patterns were obtained with high-voltage electrophoresis in the horizontal direction followed by ascending chromatography in the second direction[8]. The peptides in the patterns of the urine γ-globulins could not be superimposed upon those of the other γ-globulins and similarly the patterns for 3*S* plasma γ-globulins were different from those of the other γ-globulins: if the 3*S* plasma γ-globulins were identical to the urine γ-globulins, then the peptides of one should be identified in the peptide patterns of the other even in the presence of contaminating proteins in one or both protein preparations, and this could not be done. Virtually all of the peptides in the *S* fragment were identified in the 7*S* γ_2-globulin peptide pattern as expected.

Recently it has been suggested that the low molecular weight γ-globulins of urine and plasma are free *L* chains and that they are the normal counterparts to Bence-Jones protein. The work recorded here has demonstrated at least four low molecular weight urine γ-globulins and two low molecular weight plasma γ-globulins. The antigenic similarity between these low molecular weight γ-globulins and 7*S* γ_2-globulin was confirmed; however, immunochemical differences between the low molecular weight γ-globulins of normal urine and those of myeloma urine and those of normal plasma were also found. In addition, since *S* fragments contain *L* chains, if the low molecular weight γ-globulins contained identical *L* chains, the peptide patterns should have areas of similarity; there was no apparent similarity between the peptide patterns of *S* fragment and those of normal low molecular weight γ-globulins. The evidence as to the antigenic and peptide structure of the low molecular weight plasma and urine γ-globulins is by no means conclusive, but it would suggest that they may not be derived from nor represent components of plasma $7S$ γ_2-globulin.

Effects of 17-β-œstradiol on the Production of Acid Mucopolysaccharides by Cell Cultures of Human Fibroblasts

FIBROBLASTS from various tissues of origin have been shown to produce acid mucopolysaccharides (AMPS) *in vitro* for long periods of time up to several years[1]. It has also been pointed out that cultured fibroblasts, regardless of their original derivation, secrete predominantly hyaluronate and only small amounts of sulphated AMPS[2]. Only 'fibroblasts' growing from explants of beef embryo cartilage have been found to produce mainly chondroitin sulphate (*A* and *C*) *in vitro*[3]. This is somewhat at variance with what happens *in vivo* where different spectra of AMPS typify different tissues[4]. Nevertheless, in spite of lack of qualitative differences in AMPS secreted *in vitro*, fibroblasts grown from different tissues of origin have been found to produce different amounts of AMPS[5]. The experiments recorded here are intended to show that fibroblasts of different origin produce different amounts of AMPS *in vitro* in response to œstrogenic stimulation.

Primary cell lines were prepared from skin and soft tissues of the trunk and extremities of a 9-week-old human embryo and from foreskin of human new-borns. The cells were grown on plasma from primary explants until a good outgrowth developed. Cell suspensions were then obtained by trypsinization and used for replicate cultures. For each experiment equal aliquots of cells suspended in the medium were dispensed into several Earle *T*–30 flasks previously coated with an extremely thin layer of chicken plasma. Some of the flasks were kept as control and fed with a medium composed of Eagle HeLa medium (supplemented with glutamine) 50 per cent; whole egg ultrafiltrate 20 per cent; human placental serum 20 per cent; medium from the previous feeding period 10 per cent. The other flasks were used as experimental cultures and fed with the above medium to which 17-β-œstradiol was added in various concentrations (0·01γ, 0·05γ, 0·1γ, 0·4γ/ml.). In these circumstances, the addition of 0·01γ of 17-β-œstradiol per ml. of medium represents approximately a 5-fold increase over the amount contributed to the medium by the placental serum. The cultures of each experiment were maintained for 10 days, during which time they were washed and fed twice. The growth increment (GI) was evaluated by relating the number of cells at the beginning and at the end of each experiment. The medium from each flask was pooled separately and the AMPS extracted using the method described by Prince and Castor[6]. No attempt was made to separate sulphated and non-sulphated AMPS. Their amount was estimated as uronic acid (UA–AMPS) with the method of Dische[7]. The mean of the values for the various flasks was given as the final result of that experiment and was expressed in γ per ml. of medium. These values were then adjusted to their GI = 1. To estimate the production of UA–AMPS per cell, the total amount of UA-AMPS produced in 10 days by a culture was divided by the number of cells of that culture at 5 days. For the latter value, the mean between the total number of cells in the original inoculum and that at the end of the experiment was accepted as the closest approximation. Several experiments were carried out per each concentration of hormone. The amount of UA–AMPS present in fresh medium averaged 0·866 γ/ml. (± 0·179).

The cells from both embryonal and neonatal tissues grew rapidly and maintained the morphology of fibroblast-like cells throughout this study. Cultures which exhibited degenerative changes were excluded.

The results are summarized in Table 1. Preliminary results of some of these experiments have already been reported[8]. The control cultures of both embryonal and neonatal fibroblasts exhibited approximately the same GI and produced AMPS at about the same rate. The differences were so small as to be insignificant. The cultures of embryonal fibroblasts were exposed to 0·1 γ/ml. and 0·4 γ/ml. of 17-β-œstradiol. With both concentrations the GI was consistently smaller than that of the controls to indicate that the hormone had exerted an inhibitory effect on the growth rate of these fibroblasts. The numerical reduction of the cells in these cultures appeared to be related to decreased mitotic activity inasmuch as no cell necrosis was demonstrable. In contrast, the production of AMPS was significantly stepped up. To this end, the concentration of 0·1 γ/ml. seemed to be slightly more effective. In this connexion, it is interesting to observe that under ordinary conditions larger amounts of AMPS are produced by cultures with higher growth rate[1]. 17-β-œstradiol (0·01γ, 0·05γ, 0·1 γ/ml.) did not appear to exert any significant influence on either the growth rate

Table 1

17-β-Œstradiol (γ/ml.)	Control cultures			Experimental cultures		
	GI	UA-AMPS (γ/ml. per unit of GI)	Total UA-AMPS (γ/cell × 10^5)	GI	UA-AMPS (γ/ml. per unit of GI)	Total UA-AMPS (γ/cell × 10^5)
Embryonal fibroblasts						
0·1	1·69 (1·506–1·908)	1·676 (1·5–2·136)	0·849 (0·72–0·978)	0·906 (0·763–1·049)	4·566 (4·331–4·802)	2·402 (2·266–2·538)
0·4	1·69 (1·506–1·908)	1·676 (1·5–2·136)	0·849 (0·72–0·978)	0·975 (0·95–1·00)	3·66 (3·277–4·043)	1·861 (1·596–2·127)

0·01	1·455 (1·238–1·673)	1·533 (1·06–2·007)	1·152 (0·838–1·466)	1·392 (1·047–1·74)	1·36 (0·891–2·277)	0·97 (0·561–1·619)
0·05	1·711 (1·164–2·288)	1·56 (1·051–2·528)	1·341 (0·862–1·727)	1·673 (0·822–2·482)	1·637 (1·053–2·138)	1·16 (0·837–1·631)
0·1	1·59 (1·5–1·68)	1·172 (1·147–1·198)	1·009 (0·862–1·157)	1·451 (0·911–1·94)	1·348 (0·97–1·715)	0·898 (0·831–1·088)

of the neonatal fibroblasts or their AMPS production. Indeed, the production of UA–AMPS per cell in the experimental cultures appeared to be less than in the respective control cultures. However, it is difficult to say whether œstradiol in effect inhibited the production of AMPS by these neonatal fibroblasts since the differences between control and experimental cultures were very small.

These results indicate a definite difference between these two groups of fibroblasts in their response to stimulation by 17-β-œstradiol. The differences in GI and AMPS production when these cells are exposed to œstradiol are even better appreciated if one considers that the control cultures of both embryonal and neonatal fibroblasts have behaved in essentially the same fashion in regard to GI and AMPS production for several months of experimentation.

It should be kept in mind that these two groups of cells differ from each other not only in developmental age but also in that they are derived from different regions of the body. However, whether the difference in AMPS production *in vitro* by fibroblasts exposed to œstrogenic stimulation is attributable to the difference in their age, or in their topographical derivation or in both, is difficult to say at the present time and must wait for further investigation.

In our opinion the results reported here lend support to the contention that, functionally, there are different kinds of fibroblasts[9] which exhibit different functional properties in the face of striking morphological similarities. In addition, they indicate that functional differences among fibroblasts exist *in vitro* as well as *in vivo*.

Off-flavour of Dehydrated Carrot stored in Oxygen

WHEN dehydrated carrot is stored in the presence of oxygen its colour, due to β-carotene, is destroyed[1] and simultaneously an off-flavour develops which has been described as having an odour similar to that of violets[2]. Although it was earlier suggested that the off-flavour was due to the formation of β-ionone[2], no unequivocal proof of the nature of the product or products responsible has yet been put forward.

The substances responsible for the off-flavour of oxygen-stored carrot dice, dehydrated by the accelerated freeze drying technique[3], can be extracted with ether, and separated from the non-volatile fraction by high vacuum distillation. This fraction, on gas chromatography, gives twenty-four components only nine of which have a violet-like odour (Table 1). A further twenty-three components are present in a low-boiling fraction obtained by head-space analysis[4], but none of these smelled like violets. Of the compounds in Table 1, five, which account for more than 90 per cent of the total, have been isolated by large-scale gas chromatography and their structures investigated.

Table 1. COMPONENTS WITH A VIOLET-LIKE ODOUR ISOLATED FROM OXIDIZED DEHYDRATED CARROT

No.	Percentage total violet-like substances	Retention index at 150° PEG *A*	Identity
1	4	1,872	—
2	11	1,907	—
3	12	1,927	α-ionone
4	17	1,996	β-ionone
5	2	2,034	—
6	21	2,059	—
7	30	2,075	β-ionone 5,6-epoxide
8	2	2,204	—
9	1	2,310	—

Fraction 2 had a molecular weight (Rast) and elemental analyses corresponding to $C_{13}H_{20}O$ with 2·1 methyl groups and 2·6 double bonds. From ultra-violet and infra-red spectroscopic data it contained a methyl ketone group isolated from two conjugated double bonds one of which was alkyl substituted. The infra-red spectrum also indicated the presence of an isopropyl or gem-dimethyl group. The nature of the carbonyl group was confirmed by the properties of the 2,4-dinitrophenylhydrazine (DNP) derivatives. Gas chromatographic retention data on fraction 2 and both its catalytic hydrogenation and lithium aluminium hydride reduction products confirmed the absence of polar groups other than the ketone and the conjugated double bonds. The substance did not correspond with any known compound but probably has an ionone-like structure.

Using similar criteria, fraction 3 proved to be α-ionone; its infra-red spectrum was identical with that of a purified specimen of α-ionone and it was not separable from the authentic substance by gas chromatography using two different stationary phases at two temperatures. Lithium aluminium hydride and catalytic hydrogenation products were identical with those of the authentic specimen, as was the 2,4-dinitrophenylhydrazine derivative.

Fraction 4 was similarly shown to be β-ionone. The infra-red spectrum, gas chromatographic properties, lithium aluminium hydride and catalytic reduction products and its 2,4-dinitrophenylhydrazine derivative were identical with those of an authentic sample of β-ionone.

The data for fraction 6 corresponded best to $C_{13}H_{20}O_2$ with 1·6 methyl groups and 0·7 double bonds. The molecular weight, however, was high (253). The infra-red spectral data indicated the presence of an aldehyde, a substituted vinyl group and an isopropyl or gem-dimethyl group in the molecule. The ultra-violet absorption (λ_{max} 275 mμ ε 252) appears to indicate conjugation of the aldehyde and vinyl groups; but the infra-red evidence does not support this. The second oxygen atom is probably present as an epoxide.

By the criteria above, fraction 7 was found to be identical, with a sample of β-ionone-5,6-epoxide synthesized by the method of Karrer and Stürzinger[5].

Fractions 1, 5, 8 and 9 were not isolated in sufficient quantities for full investigation of their structures.

It would appear that the violet-like aroma of oxygen-stored dehydrated carrot is due to a number of compounds with ionone-like structures. The three of these substances which have been positively identified account for 60 per cent of the total substances with a violet-like aroma. These substances can be presumed to arise from the oxidation of carotenoids. Indeed, we have shown that the oxidation of β-carotene and β-ionone under similar conditions yields β-ionone-5,6-epoxide. α-ionone, on the other hand, may be formed from α-carotene present in the carrot. The fact that the two ionone isomers are present in similar amounts, whereas the corresponding carotenoids occur in quite different amounts (75 and 20 mg/100 g dry weight of β- and α-carotenes, respectively), probably indicates a difference in the stability of the α- and β-ionone rings.

Purification of Pinguinain by Gel Filtration

The separation and characterization of macromolecules have been recently simplified by the introduction of a useful technique which has been variously termed gel filtration[1], molecular sieve chromatography[2], restricted diffusion chromatography[3], or exclusion chromatography[4]. The formulation of the mechanism of operation of these columns has been discussed by Ackers[5]. Since the presence of more than one protein component in proteolytic enzymes isolated from plant tissue is not an unusual finding, this method should be useful in their separation. Recently, based on filtration experiments, alcohol fractionation techniques and free electrophoresis, Messing *et al.*[6,7] have identified two proteolytic components in the juice obtained from the Cuban variety of the fruit of *Bromelia pinguin* L.

We were interested in the fractionation and purification of the enzyme or enzymes present in the Puerto Rican variety of the same fruit. For this purpose, we used this type of macromolecule fractionation technique.

The juice was extracted from the fruit by squeezing the pulp in a cheesecloth. The debris was removed by centrifugation at 25,000 r.p.m. in a Spinco model *L* preparative ultracentrifuge using a swinging bucket rotor *S.W.* 25.1. Macromolecular constituents were concentrated as follows: the *p*H of the juice (which has a *p*H range of 3–4) was brought to 7·2 with 1·0 M sodium hydroxide after addition of 3 g cysteine/l. juice. A dark precipitate containing high-molecular-weight impurities, mainly carbohydrates, was formed. After centrifugation for 5 min at 2,000 r.p.m., the precipitate was discarded, the supernatant removed and brought to 0° C. Enough acetone was added to the supernatant to bring the proportion of acetone to juice to a 2:1 ratio. The precipitate formed, which contains the bulk of the enzymatic activity found in the juice, was allowed to settle for 15 min. The supernatant was discarded after centrifugation in the cold. The precipitate was redissolved in distilled water and lyophilized.

The material used for gel filtration was 'Sephadex *G*–100' obtained from Pharmacia Fine Chemicals, Uppsala (lot No. *To* 2594, particle size 140–400 mesh, water regain 10 ± 1 g/g). Columns prepared had bed dimensions 1·9 cm × 25 cm. Acetate buffer (*p*H 4·6, 0·1 M) was used as eluent. The flow of these columns was 30 ml./h.

Two-ml. samples were collected with the aid of an automatic fraction collector and analysed for protein contents and assayed for enzymatic activity. Protein contents were determined by measuring the absorption at 280 mμ in a Beckman *DU* spectrophotometer. Enzymatic assays were performed as described previously[8]. Material for the assays, iodine-131 labelled human serum albumin and normal human serum albumin (25 per cent solutions), was obtained from Volk Radiochemical Co., Skokie, Illinois, and E. R. Squibb and Sons, New York, respectively.

Experimental results indicate the presence of two macromolecules. One component appears with the void volume indicating a very high molecular weight. This component is not precipitable by trichloroacetic acid, is not rendered insoluble by heat and does not show any enzymatic activity (Fig. 1). Although absorbing at 280 mμ, its absorption maximum occurs at 330 mμ. The most abundant macromolecule shows the properties of a protein; shows absorption maximum at 280; does not absorb at 330; is rendered insoluble by heat; is precipitable by trichloroacetic acid and shows enzymatic activity proportional to protein concentration (Fig. 1). A third peak obtained contains low molecular weight peptides and amino-acids, but shows no enzymatic activity.

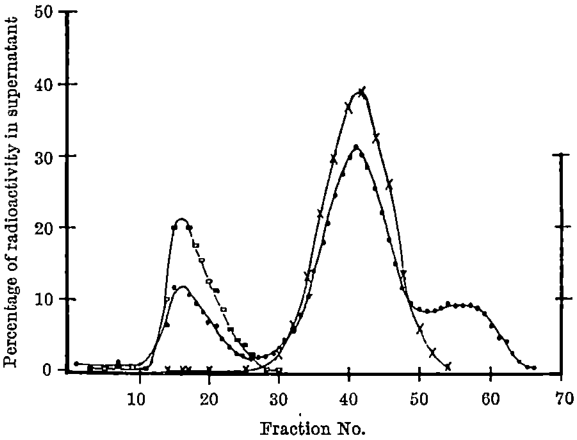

Fig. 1. Separation of pinguinain by gel filtration. Proteolytic activity was found in fractions 30–52, with a maximum in fraction 40. ×, Enzymatic activity; □, absorbancy at 330 mμ; ●, absorbancy at 280 mμ

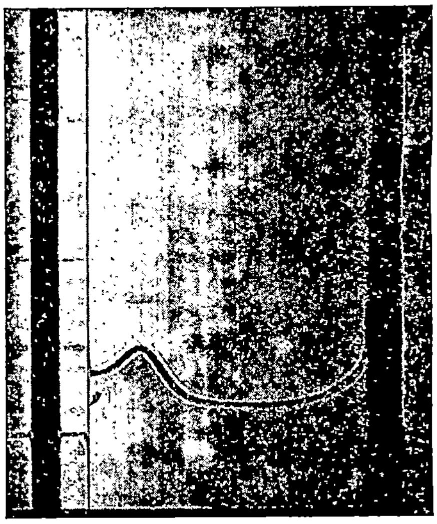

Fig. 2. Ultracentrifuge pattern of purified pinguinain. Run performed at 59,780 r.p.m. Picture taken 80 min after obtaining full speed. Direction of migration from left to right

The most abundant macromolecule migrates as a single component in paper electrophoresis in acetate buffer (*p*H 4·6, 0·05 M). Ultra-centrifugal analysis of this component, performed in a Spinco model *E* ultracentrifuge at 59,780 r.p.m. using 0·1 M phosphate buffer *p*H 7·3 as solvent, showed a single component with an $S_{20,w}$ of 2·1 *S* (Fig. 2). The diffusion coefficient ($D_{20,w}$) calculated for this purified preparation from steady state diffusion experiments using a Northrop–Anson cell was 14 ± 1·0 cm^2 sec^{-1}. The calculated partial specific volume for purified pinguinain was 0·746 ml./g. On the basis of these results and Svedberg's equation[9] a molecular weight of 14,700 ± 1,000 was calculated.

These results indicate that the Puerto Rican variety of the maya fruit contains just one proteolytic component.

It also shows that pinguinain is a protein having a small molecular weight.

Inhibitory Effect of Progesterone on Activity of Human Myometrial Adenosine Triphosphatase

During the previous investigations[1] in this laboratory human myometrial strips were exposed to progesterone until all spontaneous activity ceased and the changes in the concentration of adenosine triphosphate (ATP) and phosphocreatine (PC) measured. Until such paralysis had existed for at least 40 min, no significant change in high-energy phosphate bonds (ATP and PC) could be documented. It was, therefore, concluded that in the earlier stages of the myometrial inhibition progesterone might be exerting its effect in the utilization of ATP rather than in its synthesis. As a continuation of the investigations on this problem, the effect of progesterone was then determined on the ATPase activity of the human myometrial strips. This communication deals with the results obtained.

The method of DuBois and Potter[2] was used to determine the ATPase activity in which human non-pregnant myometrial tissue homogenate was incubated in the presence of calcium chloride, diethyl barbiturate (buffer) and ATP. The amount of inorganic phosphorus liberated in homogenate corresponding to 6 mg and 9 mg wet weight tissue in 15 min at 37° C as determined by the procedure of Rockstein and Herron[3] was taken as a measure of ATPase activity. One microgram of phosphorus liberated was interpreted as one unit of ATPase activity. Ten to 300 μg of progesterone dissolved in 30λ of propylene glycol was added to the homogenate to determine its effect.

The two requirements: (*a*) that the rate of reaction is linear during the time of incubation; (*b*) that the rate is directly proportional to the amount of enzyme present in the test system, should be fulfilled if any enzyme assay is to be found satisfactory.

Propylene glycol used as a vehicle (30λ) did not alter the ATPase activity. Progesterone in concentrations of more than 10 μg (and up to 50γ tested) per mg wet weight human myometrial tissue was found to inhibit the human myometrial ATPase activity on an average of 27·3 per cent ($P < 0{\cdot}001$) based on 15 experiments as shown in Table 1.

It is interesting to note that such high concentrations of progesterone were needed to inhibit the human myometrial ATPase activity. It may be that the smaller concentrations of progesterone might inhibit the ATPase activity when exposed to spontaneously contracting myometrial strip in muscle-bath preparation over a prolonged period of time. Such an investigation is in progress and the results will be reported later.

Table 1

No. of cases	Average ATPase activity in units of human myometrial tissue/mg wet weight* Control	Progesterone treated (90–300 μg)	Average reduction in ATPase activity by progesterone
15	1·98	1·44	0·54 (27·3%)†

* 1 ATPase unit = 1 μg phosphorus liberated.
† $t = 7{\cdot}09$.
$P < 0{\cdot}001$.

Stimulation of Glucose Utilization by Insulin in Human Adipose Tissue Homogenates

To date no effect of insulin on utilization of glucose in a cell-free preparation has been described. Indeed, the apparent ineffectiveness of insulin in cell-free preparations was a major clue to the discovery of the insulin stimulation of trans-membrane transport. We have been examining utilization of glucose in human adipose tissue and have observed a distinct stimulation of utilization of glucose by insulin added to homogenates of omentum.

Omentum was obtained from subjects undergoing abdominal surgery being performed for reasons other than malignancy. Homogenization was achieved within 15 sec, using a 'Vir Tis 23' homogenizer in a Krebs–Ringer bicarbonate buffer[1] gassed with $O_2 : CO_2$(95 : 5) to *p*H 7·4. The potassium chloride concentration of the buffer was doubled at the expense of the sodium chloride. A 'defatted' homogenate was obtained by removing the supernatant layer of congealed fat formed during centrifugation in the cold at 500*g* for 10 min. The homogenate was then supplemented to give final concentrations of 0·001 M ATP, 0·001 M TPN$^+$, 0·005 M Mg^{++} and 5·6 mM glucose. Incubation vessels containing 1 ml. of homogenate were incubated for 1 h at 37° C with agitation at 60 cycles/min. Insulin was added to give a concentration of 0·1 unit/ml. homogenate. Glucose was measured by a micro adaptation of the glucose oxidase method of Sunderman and Sunderman[2].

Table 1. Stimulation of Glucose Utilization by Insulin in Human Adipose Tissue Homogenates

Glucose utilization μg/mg tissue N_2/h	Without insulin	With insulin	Δ Insulin
	279 ± 75	466 ± 246	187 ± 105*

Values are means ± *S.D.* in 11 experiments
* $P < 0{\cdot}01$.

As seen in Table 1, insulin produced a 67 per cent increase in glucose disappearance. Though there is indirect evidence of an intracellular action of insulin on both carbohydrate[3] and protein metabolism[4], we believe that this is a direct demonstration of an intracellular insulin effect on utilization of glucose. Previous inability to show such an effect may have been due to the choice of tissue and incubation conditions.

Presence of Carbonate in a Low-density Fraction of Diaphyseal Bone

USING a method of centrifugation in liquids progressively increasing in specific gravity[1], it is possible to separate, from a sample of bone powder, fractions at various degrees of mineralization[2]. These fractions, which can be recovered quantitatively, can then be analysed by appropriate chemical and biophysical techniques. We used infra-red spectroscopy for the examination of the carbonate present in bone, comparatively for a low specific gravity fraction (1·7 g/c.c.) and a pool of the high specific gravity fractions (1·8–2·3 g/c.c.) derived from diaphyseal bone samples of normal rats. It must be pointed out that less than 0·5 per cent of the samples belonged to the 1·7 gravity fraction. We used a Perkin–Elmer 221 infra-red spectrophotometer equipped with a sodium chloride prism. Potassium bromide pellets were prepared with various concentrations of whole unashed diaphyseal bone after separation.

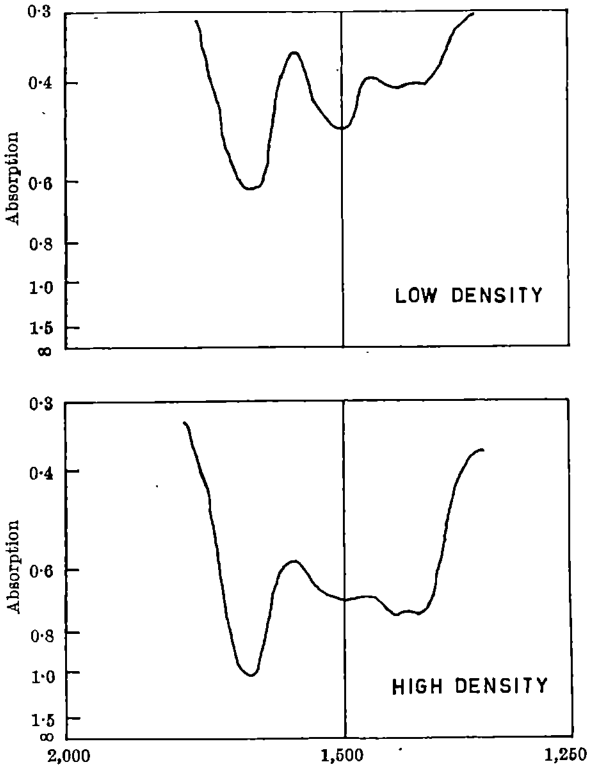

Fig. 1

Of the three regions of infra-red absorption by carbonate groups[3], two were satisfactorily demonstrated (860–875 cm^{-1} and 1,400–1,500 cm^{-1}) in both the low and the high specific gravity fractions. No absorption was observed at 710 cm^{-1}. Table 1 gives the location and intensity of all the absorption bands and Fig. 1 shows the spectra recorded between 1,300 and 1,700 cm^{-1}. In that region, three carbonate bands can be seen located at 1,506, 1,433, 1,401 cm^{-1} and 1,501, 1,433, 1,408 cm^{-1} respectively for the low and the high specific gravity fractions; but their relative intensity differs: in the low specific gravity fraction, the band located at 1,506 cm^{-1} is more intense than the bands found at 1,433 and 1,401 cm^{-1}, whereas the reverse is true in the high specific gravity pool. In both spectra, the band located at 1,639 cm^{-1} can be attributed to adsorbed water. The band located at 866 cm^{-1} was poorly resolved and showed no apparent difference from one spectrum to the other.

Two facts emerged from these results: (*a*) carbonate is present in both the early-calcifying and the fully mineralized parts of bone; (*b*) the change in the relative intensities of the three carbonate bands found in the 1,400–1,500 cm^{-1} region indicates that carbonate is present in more than one chemical form and/or environment, the proportion of which differs in the low and the high specific gravity fractions[4-6].

Table 1. FREQUENCIES OF THE ABSORPTION BANDS (CM^{-1})

Origin of the band	ν_3 $CO_3^{=}$	ν_2 $CO_3^{=}$	$PO_4^{\equiv}$	H_2O
Material				
Low density	1,506 m 1,433 w 1,401 w	868 w	ca 1,050 sb	1,634 s
High density	1,501 vw 1,433 w 1,408 w	868 w	ca 1,050 sb	1,639

Chemical analysis for carbon dioxide could not be carried out because only very small amounts of the low density material were available; this, however, appears to be critical before trying to propose any further interpretation of the infra-red data.

Action of Rifamycin on Incorporation of Amino-acids into Protein in Cell-free Systems from *B. subtilis*

RIFAMYCINS are new antibiotics[1,2] having a marked inhibitory effect on the growth of many Gram-positive bacteria, including staphylococci[3,4], and have already been shown to affect bacterial respiration[5]. In this communication some results are reported concerning the effect of rifamycin *SV* and rifamycin M_{14} on the incorporation of amino-acids into protein by cell-free extracts of *B. subtilis* strain A.T.C.C. 6633.

Rifamycins have no effect on amino acyl-adenylate formation as studied by measuring the ATP-^{32}P pyrophosphate exchange or on amino acyl-RNA formation. Results of these experiments are shown in Tables 1 and 2. Fig. 1 shows that rifamycin does not affect pyruvate kinase activity as measured by the method reported by Bücher *et al.*[6].

For the examination of the incorporation of L-isoleucine labelled with carbon-14 into proteins by cell-free extracts, *B. subtilis* strain A.T.C.C. 6633 was cultivated in a medium containing 1·2 per cent casamino-acid, 0·3 per cent glucose, 0·1 per cent yeast extract, 0·45 per cent KH_2PO_4, 0·12 per cent $MgSO_4$, 0·81 per cent $NaHPO_4$. Cells were collected during logarithmic growth phase and disrupted by grinding with alumina Norton.

Results obtained using crude extracts prepared according to the method of Tissières[7], and by using washed ribosomes and 105,000*g* supernatant (*S*–105) prepared

Table 1. AMINO-ACID-DEPENDENT ATP-^{32}P-PYROPHOSPHATE EXCHANGE

	Additions	Percentage exchange
Complete mixture		55
,, ,,	− amino-acids	25·5
,, ,,	+ 0·0015 μmole/ml. rifamycin *SV*	56
,, ,,	+ 0·015 μmole/ml. rifamycin *SV*	55·4
,, ,,	+ 0·03 μmole/ml. rifamycin *SV*	50·4

The reaction mixture contained the following in μmole/ml.: 50 *tris*-HCl *p*H 7·4; 10 $MgCl_2$; 10 ATP; 10 each of 20 L-amino-acids; 10 ^{32}P-pyrophosphate (specific activity 14,000 c.p.m./μmole); 1·5 mg/ml. homogenate protein. ATP-^{32}P pyrophosphate exchange was measured as described by Demoss *et al.* (ref. 9). Radioactivity was determined by a windowless gas-flow counter.

Table 2. L-ISOLEUCYL-*s*RNA FORMATION

	Additions	c.p.m./mg *s*RNA
Complete mixture		194
,, ,,	+ 0·03 μmole/ml. rifamycin *SV*	188

2	Complete mixture		1,500	
	,, ,,	+ 0·03 μmole/ml. rifamycin *SV*	1,020	40
	,, ,,	+ 0·03 μmole/ml. rifamycin M_{14}	636	72
	,, ,,	deproteinized at zero time	300	

The reaction mixture contained the following in μmole/ml. In exp. 1: 10 *tris*-HCl *p*H 7·4; 10 magnesium acetate; 40 KCl; 0·34 ^{14}C-L-isoleucine (specific activity $2·68 \times 10^6$ c.p.m./μmole); 0·2 GTP; 1 ATP; 10 phosphoenolpyruvate; 84 μg/ml. pyruvate kinase; 120 μg/ml. DNA prepared by the method of Marmur (ref. 12); 2 mg/ml. homogenate protein prepared by the method of Tissières *et al.* (ref. 7). In exp. 2: 100 *tris*-HCl *p*H 7·4; 12 magnesium acetate; 50 KCl; 6 mercaptoethanol; 0·05 each of 20 L-amino-acids minus isoleucine; 0·17 ^{14}C L-isoleucine (specific activity $2·68 \times 10^6$ c.p.m./μmole); 0·03 GTP; 1 ATP; 5 phosphoenolpyruvate; 20 μg/ml. pyruvate kinase; 120 μg/ml. DNA (ref. 12); 1·2 and 0·6 mg *S*-105 and ribosomal protein prepared following the method of Matthaei and Nirenberg (ref. 8). In both cases the reaction was stopped with perchloric acid by the method of Ofengand *et al.* (ref. 13). Radioactivity was determined by a windowless gas-flow counter.

according to the method of Matthaei and Nirenberg[8], are given in Table 3.

These results indicate that rifamycin is an effective inhibitor of ^{14}C-L-isoleucine incorporation into proteins at molar concentrations much lower than those which produce the same inhibition by chloramphenicol or by other antibiotics active on protein synthesis[14-15].

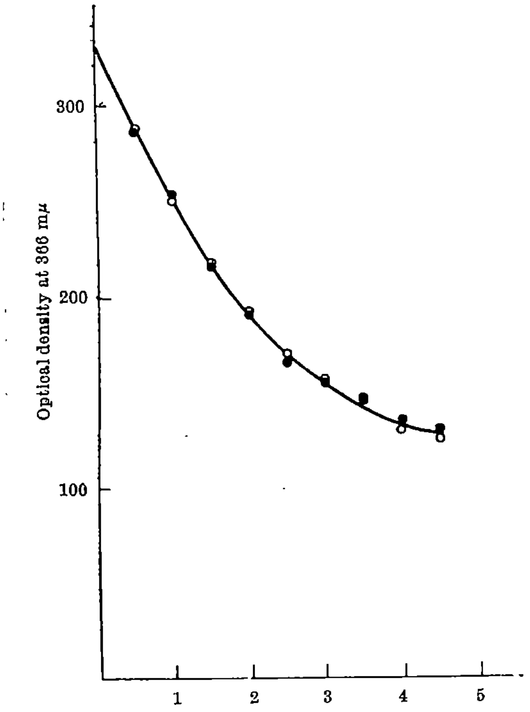

Fig. 1. Effect of rifamycin on pyruvate kinase activity, as measured by the method of Bücher *et al.* (ref. 6). ○, Without rifamycin; ●, in the presence of 0·075 mM rifamycin *SV*

Experiments are in progress to determine at which level the inhibition is effective.

PHYSIOLOGY

Occurrence of Urinary Calculi in Rats exposed to High Concentrations of Oxygen with Added Carbon Dioxide

IN the course of an investigation[1] of the pulmonary responses of animals exposed to high concentrations of oxygen at atmospheric pressure (OAP) and to high concentrations of oxygen at atmospheric pressure to which 9–13 per cent carbon dioxide was added (OAP + CO$_2$), discrete, amorphous, non-crystalline masses were found in the urinary bladder at autopsy.

A total of 383 Sprague–Dawley male rats weighing 200–250 g were used in nine experiments. In each experiment 15–20 rats were exposed to OAP, another 15–20 to OAP + CO$_2$ and a third group of 8–12 were maintained in air. Each group had the same food and environmental temperature. Specially constructed identical chambers were used. The animals were observed frequently and autopsied after 40–60 h. Bladder masses, if present, were weighed (11·6 mg average) and their amino-acid composition was examined in a few cases.

The results of the observations of urinary calculi are presented in Table 1.

Table 1

	Air controls	OAP	OAP + CO$_2$
Total No. of rats	85·0	162·0	136·0
No. of rats in which masses were observed	4·0	32·0	61·0
% of total number showing masses	4·7	19·7	44·8

χ^2 comparison of OAP with air controls $P < 0·005$
χ^2 comparison of OAP with OAP + CO$_2$ $P < 0·001$

Two-dimensional chromatographic analysis of the calculi hydrolysed with 6 N hydrochloric acid indicated the presence of cysteine, histidine, arginine and/or lysine, aspartic acid, serine, glutamic acid, glycine, threonine, alanine, tyrosine, valine or methionine, proline, phenylalanine and leucine or isoleucine.

These results show a significant increase in the occurrence of urinary calculi after exposure to oxygen at atmospheric pressure for 2–3 days. The addition of carbon dioxide to the oxygen environment further significantly increased this tendency for calculus formation.

Signs of oxygen toxicity developed in both OAP and OAP + CO$_2$ rats during these experiments. At autopsy these animals showed hæmorrhagic and œdematous lungs, hydrothorax and a tendency for bleeding from the nose and mouth. These findings are typical of oxygen poisoning. In the air controls 2 of the 4 rats showing calculi also presented gross evidence of pulmonary lesions. It appears reasonable, therefore, to relate the formation of the calculi to hypoxia and hypercapnia which may exist in the late stages of oxygen poisoning. Since addition of carbon dioxide was associated with an increase in the incidence of calculi it is possible that hypercapnia and the attendant respiratory acidosis with consequent alteration of urinary *p*H predispose to the development of these urinary calculi. Anoxia as a cause cannot be ruled out since, at least in dogs exposed to OAP, severe anoxia develops immediately before death[2]. In these experiments autopsy of rats killed before the terminal stages of oxygen toxicity reveals bladder calculi both in OAP and in OAP + CO_2 animals. The significantly greater incidence of calculi in the latter case would argue in favour of hypercapnia as an aggravating condition since they are definitely hypercapnic but not necessarily hypoxic. In either case development of calculi is coincident with evidence of respiratory distress.

These findings are of interest in conjunction with the report by McGaughey[3] of excretion of uncrystallized urinary calculi in dystrophic mice. Muscular dystrophic animals frequently have compromised respiratory mechanics; therefore the development of calculi may be associated with the hypoventilation.

Selective and Directional Transfer of 7*S* γ_2-Globulin across the Human Placenta

RABBIT γ_2-globulin can be hydrolysed by papain into three polypeptide fragments which are nearly equal in size: two of these fragments, I and II, each possess an active antibody site, whereas the third fragment, III, has no antibody activity[1]. Brambell *et al.* examined the maternofœtal transfer of such fragments in the pregnant rabbit, and reported that the amount of fragment III to be found in the fœtus after administration to the mother was 6–10 times the amount of fragments I or II and only a fourth the amount of the parent γ_2-globulin[2]. It was concluded that the fragments pass from mother to fœtus less readily than does the intact γ_2-globulin molecule, and that the transmissibility of γ_2-globulin from doe to fœtus is attributable to that part of the molecular structure represented by the non-antibody fragment. In the study reported here, this concept was reinvestigated as to its applicability to the metabolism of 7*S* γ_2-globulin in man.

Human 7*S* γ_2-globulin (Lot 330–2, Squibb) was hydrolysed with papain[1]. The *F* fragment, which is analogous to fraction III from rabbit γ_2-globulin, and the *S* fragments, or those components analogous to fractions I and II from rabbit γ_2-globulin, were isolated from the hydrolysate[3]. γ_u-Globulins having an average sedimentation coefficient of 1·5*S* were isolated from the pooled urine of normal adults[4]. The *S* and *F* components, the parent 7*S* γ_2-globulin and the 1·5*S* γ_u-globulins were iodinated with iodine-131 as described elsewhere[5].

Normal women in the last month of pregnancy were begun on 100 mg of potassium iodide orally per day, and then each received a single injection of less than 0·2 μc./kg body-weight of one of the radioiodinated proteins at a given time prior to delivery. The concentrations of radioactivity precipitable in 10 per cent trichloroacetic acid present in maternal sera at 10 min and again during delivery of the infant were determined, as were the concentrations in umbilical cord sera and in amniotic fluid. The concentrations of unlabelled 7*S* γ_2-globulin in maternal and fœtal sera and in amniotic fluid were determined immunochemically[5].

In Fig. 1, the concentration of labelled protein found in the serum of the infant at birth, C_f, relative to that found in maternal serum, C_m, at the same time, or C_f/C_m, is expressed as a function of time. It would appear that the transfer of *S* fragment, *F* fragment and γ_u-globulin from mother to fœtus exceeded the maternofœtal transfer of 7*S* γ_2-globulin and that *S* fragment as well as γ_u-globulin, which is related structurally to *S* fragment, traversed the maternofœtal barrier as readily as did the *F* fragment. These conclusions are quite different from those reached by Brambell *et al.*[2]; but it must be noted that the latter investigators related the amount of labelled protein found in the fœtus to the amount which was placed in the uterine lumen 24 h earlier without regard to possible differences in the turn-over rates of the various proteins: although two labelled proteins may cross the maternofœtal barrier at the same rate, a difference in their rates of catabolism will be reflected in differences in their concentrations in the maternal circulation over any period of time and this in turn will result in differences in their concentrations in the fœtus at any given moment. In the work recorded here, the half-lives for the different labelled proteins in the mother were found to be 20 days for 7*S* γ_2-globulin, 4 days for *F* fragment, 0·4 days for γ_u-globulin and 0·3 days for *S* fragment. By relating the concentration of labelled protein in the fœtus to that in the mother at the same time, C_f/C_m (Fig. 1), a correction was, in effect, introduced for the differences in the rates of disappearance of these proteins from the maternal circulation.

The concentration of 7*S* γ_2-globulin averaged approximately 1·7 g/100 ml. in both maternal and fœtal sera and 0·19 g/100 ml. in amniotic fluid. Amniotic fluid was obtained at delivery of five mothers given labelled 7*S* γ_2-globulin. Of four amniotic fluids obtained 4 h

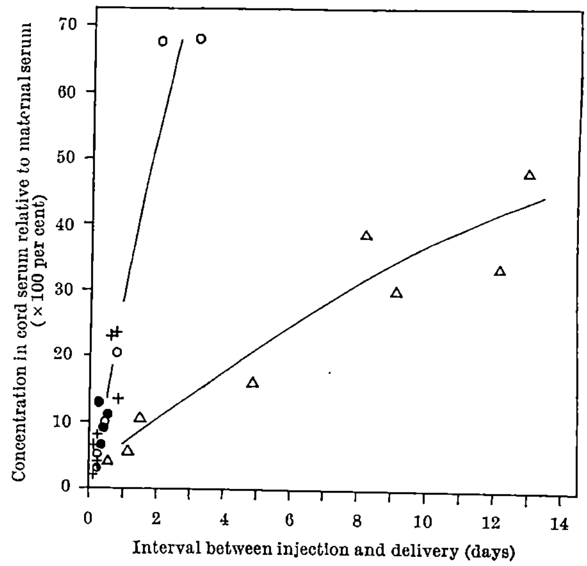

Fig. 1. Concentrations of labelled proteins in cord serum of the infant at birth relative to the concentrations of these proteins in the maternal serum at delivery: 7*S* γ_2-globulin (triangles), *S* fragment (solid circles), *F* fragment (hollow circles), and γ_u-globulin (crosses). The half-lives of *S* fragment and γ_u-globulin were 0·3 and 0·4 days respectively in the mother

after injection, no labelled protein could be detected in 2, while 2 had only 0·1 per cent of that in maternal serum; the corresponding cord sera contained 1·2–1·9 per cent of that in maternal serum. The remaining amniotic fluid, obtained approximately 23 days after injection, contained no detectable labelled protein, while the cord serum concentration was 125 per cent of that in the maternal serum. Thus, the specific activity, or counts per mg of γ_2-globulin, in amniotic fluid was lower than that in cord serum and the primary site of transfer of $7S$ γ_2-globulin to the fœtus was not via amniotic fluid. The placenta would appear to be the probable site of transfer, therefore, as has been demonstrated in the rhesus monkey[6].

The results also suggest that the permeability of the placenta to $7S$ γ_2-globulin in the direction of mother to fœtus is greater than that in the direction of fœtus to mother. The fœtus at term does not synthesize $7S$ γ_2-globulin[7]. Thus, the amount transferred from mother to fœtus, T_{mf}, must equal the amount degraded by the fœtus, A, plus the amount, T_{fm}, which passes from fœtus to mother, or $T_{mf} = A + T_{fm}$. The half-life of $7S$ γ_2-globulin in the newborn infant in this work was found to be relatively constant from birth and averaged 16 days; it would seem reasonable to assume that the fœtus at term just prior to delivery also catabolized $7S$ γ_2-globulin and that A is finite and significant. Therefore, T_{mf} would appear to be greater than T_{fm}. This directional difference in the permeability of the placenta to $7S$ γ_2-globulin would seem to explain why the fœtal serum concentration of this protein attains a level similar to that in the maternal serum despite fœtal catabolism of the protein and despite absence of synthesis of the protein by the fœtus. It also serves to explain why the serum concentration of $7S$ γ_2-globulin in the infant at birth may even be higher than that in the mother as is often found.

Flow of Blood to the Pineal Body of the Rat

NUMEROUS cytological and histochemical observations indicate a secretory function for the pineal body of higher vertebrates[1,2]. Physiologically also, the pineal body of the rat satisfies most of the criteria for an endocrine organ[3-5]. Although anatomical evidence suggests that rat and mouse pineal vascularity is less than in some classical endocrine organs[6,7], in view of the relatively high blood flow rate to endocrine structures in general[8], it is reasonable to expect the pineal to be similarly well perfused. We have found that the minimum rate of rat pineal blood flow per g exceeds that of most endocrine organs, equals that of the neurohypophysis and is surpassed only by that of the kidney.

Pineal body blood flow was measured by a variation of Sapirstein's isotope indicator method which has been utilized successfully for other organs[9]. Briefly, the method depends on the fact that the quantity of radioactive rubidium or potassium indicator taken up by an organ is proportional to the blood flow through that organ, provided that the organ has the same extraction ratio toward the indicator as the body as a whole during the first minute after injection. This can be demonstrated if during this time uptake of the indicator by the organ remains unchanged, despite continuing recirculation; under such conditions, the ratio between organ uptake and body uptake of indicator is equal to the ratio between organ blood flow and cardiac output. If, on the other hand, the organ fails to retain its indicator after initial arterial delivery, as in the case of brain with respect to rubidium or potassium, then organ blood flow is underestimated. When a part of the body is non-homogeneous, such that the indicator is rejected by one part and taken up by another, there will be an initial peaking of the organ indicator content followed by a steady but lesser elevation[10,11]. Blood flow fractions can be estimated from the peak value of indicator content, but may underestimate true flow values considerably.

Fractions of the cardiac output perfusing the pineal body were independently measured as follows: In one laboratory (H. G.) rubidium-86 solution was rapidly injected through a chronically implanted femoral vein catheter in 185–225-g male and female Wistar rats anæsthetized with pentobarbital. The animals were decapitated 5 sec, 10 sec, 20 sec, or 60 sec later. In the other laboratory (R. W.) potassium-42 was rapidly injected through the tail veins of restrained, unanæsthetized, female Sprague–Dawley rats weighing about 200 g. These animals were decapitated 15 and 60 sec later. The pineal tissue was rapidly weighed and the organ fractional uptake of rubidium-86 or potassium-42 was measured in a γ-sensitive well counter.

The fractional uptake of rubidium-86 by the pineal body was very high at 5 sec after isotope delivery (Fig. 1). This indicates that no less than 0·0085 per cent of the cardiac output, or 8 per cent/g, perfused the organ. Rubidium-86 content then fell precipitously by a half to a relatively flat plateau 15–55 sec later. The 5-sec value differed significantly from those at 20 sec or 60 sec at the 0·001 level. There were no sex differences. A similar plateau (3·5 per cent/g) was found between 15 and 60 sec after injection of a potassium-42 indicator in another strain of rat at rest and without anæsthesia (Fig. 1).

On the basis of the rubidium-86 plateau figure and cardiac output values determined in a separate but comparable group of animals (about 250 ml./min/kg), the estimated minimum pineal body blood flow in the anæsthetized Wistar rat is 2 ml./min/g. A closer approximation to the true blood flow, based on the peak figure, is 4 ml./min/g; experience with similar peaks in nervous tissue leads us to believe that even this figure is below the true value.

The pineal body and whole brain[10,11] behave similarly toward alkali metal isotopes so far as the early time course of label is concerned. Later, the plateau value for whole brain is very low; that for the pineal body is about half the peak value. This suggests that the pineal is a two-compartment system. The first compartment loses its isotope content rapidly within 10 sec either by rejection, as in nervous tissue, or by shunting through arterio-venous anastomoses. The second compartment with a large and accessible reservoir captures its rubidium and retains it for a minute or longer, resembling non-nervous tissue such as thyroid or heart. Curve 1, an extrapolation of the peak figure, describes pineal isotope content as if it were composed entirely of nervous tissue. Curve 2, an extrapolation of the plateau, describes pineal rubidium content as if it were heart. A resultant curve closely resembling

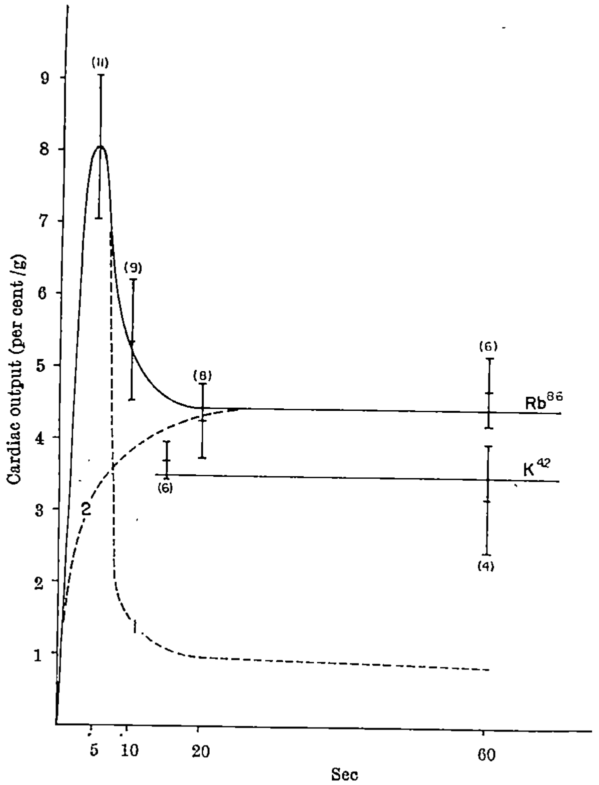

Fig. 1. Minimum pineal blood flow calculated from fractional uptake of ^{86}Rb or ^{42}K at different times after injection presented as per cent of cardiac output per g wet weight ± *S.E.* The numbers of animals in each group are in parentheses. Theoretical pineal behaviour towards ^{86}Rb based on all 'nervous' or 'non-nervous' tissue composition is presented in curves 1 and 2, respectively

our findings would be generated if the two tissue compartments were equally well perfused.

The structural correlates of these two physiological compartments are not yet clarified. An isotope peak, due to trapping in the blood vessels at the instant of death, indicates either rejection or *A–V* shunting. Since pineal body *A–V* shunts have not yet been described and a considerable mass of sympathetic nerve endings of extra-pineal origin terminates in the pineal perivascular spaces[12,13], the more reasonable hypothesis is that this sympathetic tissue constitutes at least part of a rubidium rejecting compartment.

HISTOCHEMISTRY

Carbonic Anhydrase in the Mamillæ of the Hen's Egg Shell

THE shell of the hen's egg is formed in the oviduct of the hen within 19 h, and in this shell 5 layers can be morphologically differentiated. From the inner to the outer layer are, in consecutive order, the inner egg membrane, the outer egg membrane, the mamillæ, the matrix, and, finally, the cuticle. The egg which passes into the uterus is already covered by the inner and outer egg membranes; but whether the mamillæ are already formed in the isthmus or only later in the uterus has not been definitely established. The mamillæ and the egg shell matrix which are formed in the uterus are consequently incrusted with an inorganic substance which consists mainly of calcium carbonate. The porous cuticle finally surrounds the calcified egg shell on the outside. The CO_3^{--} ion as well as the calcium is of equal significance in the calcification process of the egg shell.

The observation that sulphonamides[1-3] and Cl^- ions[4] which inhibit the carbonic anhydrase *in vitro*, and which also influence the quality of the egg shell, has confirmed the supposition of Meldrum and Roughton[5] that the enzyme carbonic anhydrase plays a part in the calcification of the egg shell.

Carbonic anhydrase catalyses the reaction: $CO_2 + H_2O \rightleftharpoons H_2CO_3$ and was demonstrated in the uteri of laying hens[6]. We were able to show that the enzyme is predominantly situated at the apical pole of the epithelia of the tubular glands[7]. These glands release the Ca^{++} ions as well as the HCO_3^- ions into the lumen of the uterus.

Robinson and King[8] have reported on the histochemical demonstration of carbonic anhydrase in the region of the mamillæ in the egg shell. As the mamillæ which contain mucopolysaccharides are able to increase the concentration of calcium ions, the presence of carbonic anhydrase in these formations would be of extraordinary significance for the understanding of the calcification.

So far extracellular localized carbonic anhydrase was, of course, never demonstrated, and we know from our own experience that the histochemical demonstration of the enzyme is difficult and it must be very critically judged in respect to its specificity. Therefore it seemed justifiable to us to repeat the examinations of Robinson and King, and to submit the results to a test.

For the tests, partly freshly laid eggs of White Leghorns were used, and partly uncalcified egg shells which had been taken from the uterus of the same breed.

Decalcification proceeded according to Robinson and King[8] in disodium ethylenediamine tetraacetic acid with *p*H 8·5 and at 4° C. We followed the progress of the decalcification process by the use of a polarizing microscope.

The decalcified egg shells were torn up with pincers into pieces about 4 mm² large, a part of which was subjected to the periodic acid–Schiff reaction according to McManus[10]. The activity of the carbonic anhydrase was examined according to Häusler's method[11]. 'Diamox' (acetylamino-1,3,4-thiodiazole sulphonamide-5) or potassium cyanide was added to single incubating media:

Incubating media:
- (*a*) According to Häusler
  $CoSO_4$ (0·1 mol) 1 ml.
  H_2SO_4 (0·05 mol) 6 ml.
  $NaHCO_3$ 1 g
  Na_2SO_4 (0·1 mol) 50 ml.
- (*b*) Medium as above + 5 × 10^{-3} mol 'Diamox'.
- (*c*) Medium as above + 4 × 10^{-2} mol 'Diamox'.
- (*d*) Medium as above + 1 × 10^{-4} mol KCN.
- (*e*) Medium without $NaHCO_3$ (*p*H 7·5 was adjusted with *tris* buffer).

After an incubation period of 1 h at room temperature the cobalt carbonate was changed in the usual way, after thorough watering, into cobalt sulphide. The preparations were dehydrated and mounted with 'Entellan'.

After incubation for 60 min without the addition of inhibitors the preparations show a pattern of blackish brown, apparently enzymatic spots, distributed evenly across the outer egg membrane (Fig. 1). The pattern of distribution of these spots and their size correspond to the picture of the periodic acid–Schiff reaction. It is a question of the mamillæ which on account of their higher mucopolysaccharide content are to be seen as red zones in the periodic acid–Schiff reaction (Fig. 2).

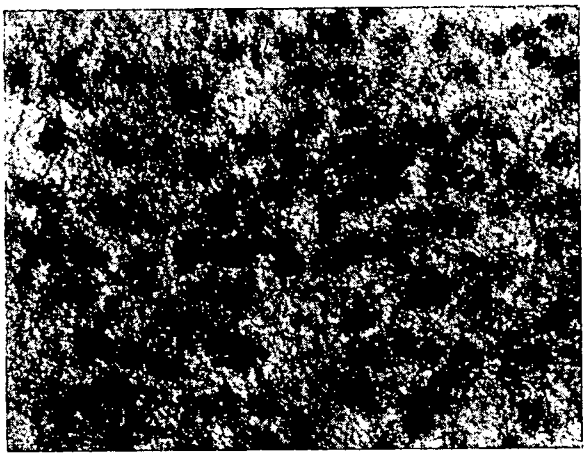

Fig. 1. Surface view of the decalcified egg shell. The mamillæ appear as black spots on the outer egg membrane. Carbonic anhydrase according to Häusler (×60)

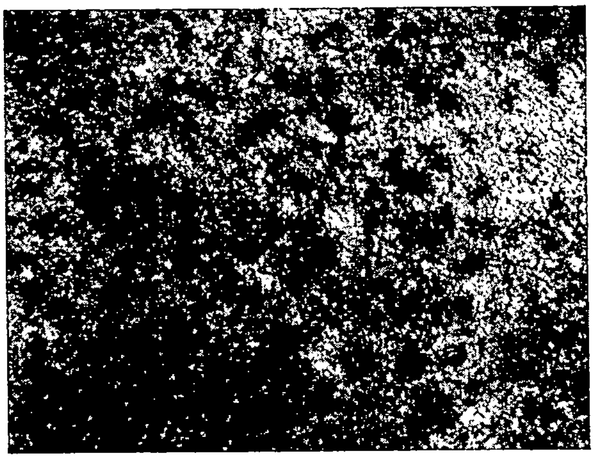

Fig. 2. Periodic acid–Schiff reaction. The mamillæ can be recognized as black spots by their higher mucopolysaccharide content (×60)

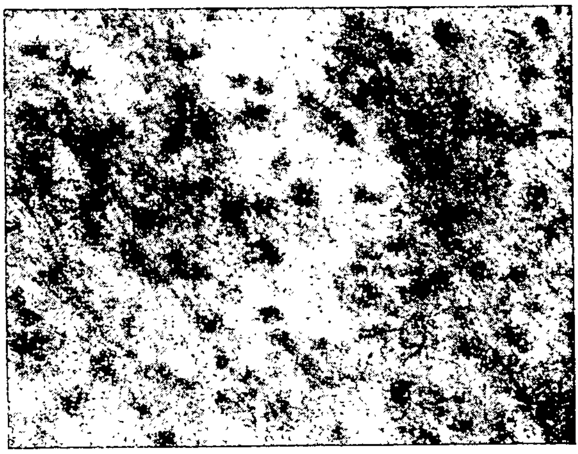

Fig. 3. Carbonic anhydrase according to Häusler. Addition of 4×10^{-2} mol 'Diamox' (×60)

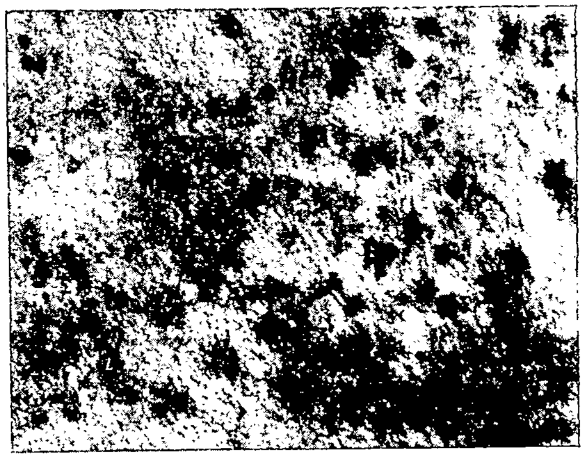

Fig. 4. Carbonic anhydrase according to Häusler. Incubation medium without sodium bicarbonate (×60)

However, in contrast to Robinson and King, we could neither inhibit the enzymatic reaction by the addition of 5×10^{-3} mol 'Diamox', which is sufficient to block completely the carbonic anhydrase in kidney sections and red corpuscles, nor suppress only partly the reaction by the addition of 4×10^{-2} mol 'Diamox' (Fig. 3). The same result followed the addition of potassium cyanide.

These observations demonstrate that it is here a question of an unspecific, non-enzymatic reaction of the mamillæ. For even with medium (*e*) the same reaction ensues in the mamillæ (Fig. 4). Consequently the reaction here also occurs in the absence of the substrate enzyme.

Evidently cobalt ions are bound to the mucopolysaccharides of the mamillæ. In order to verify this, the following model experiment was carried out.

1 ml. of a solution of 0·1 mol cobalt sulphate was mixed with 20 ml. of ethanol and added to 20 mg of chondroitin sulphuric acid in the form of its sodium salt. This mixture was put in a centrifuge and the residue was carefully washed out several times with altogether 100 ml. of ethanol. A sharp blackening effect which is due to the formation of cobalt sulphide could be distinguished in the residue after staining with an aqueous or even alcoholic ammonium sulphide solution.

The mamillæ of the egg shell contain mucopolysaccharides[9] which probably consist of up to 40 per cent chondroitin sulphuric acid[12]. These mucopolysaccharides can bind Co^{++} ions as well as other double valued positive ions. So, in the course of a histochemical carbonic anhydrase demonstration, enzymatic activity of the carbonic anhydrase is simulated by the Co^{++} ions which are bound to the mucopolysaccharides of the mamillæ.

Fatty Metaplasia of the Filum Terminale of the Frog

THE following observations were made during a search for preparations which would permit assays of various enzymes in tissue samples containing glial cells only. Such an opportunity seemed to be provided by the filum terminale which is commonly considered a glial remnant of the fœtal sacral cord[1]. Tobias, Clark, and Gerard[2] measured the respiration of the filum terminale of the cat and concluded that glial tissue had a rather high rate of respiration, comparable to that of neurones. The filum terminale of *Rana catesbiena* was used in our work because of its unusual size. A smaller material of 8 specimens of *Rana pipiens* was also examined with the same results.

Assays of the frog filum terminale indicated very little, if any, succinic dehydrogenase activity but extremely variable DPN-diaphorase activity per wet weight or per mg of protein. Searching for histological differences which might reflect this variability, we found that the filum terminale of normal frogs undergoes various degrees of fatty metaplasia. Although we have not found previous reference to this in the literature, fatty metaplasia of the filum terminale of the frog seems to be a physiological phenomenon; we could not relate it to the state of health or nutrition of the frogs; it did not seem to represent a pathological fatty degeneration because the fatty changes were confined to the filum and no fatty changes were seen in the spinal cord. All our frogs were studied during summer and autumn. The extent of fatty metaplasia was usually the same throughout any given filum, but it varied greatly among animals. The following observations were made in histochemical preparations for lactic dehydrogenase and DPN-diaphorase which were counterstained with fat red; longitudinal and transverse sections of the filum were used.

'Normal' glial cells in the filum terminale of the frog showed intense lactic dehydrogenase and DPN-diaphorase activity throughout their cytoplasm and processes (Fig. 1). Compared with glial cells in mammalian brains, these cells could not be identified as being either astrocytes or oligodendroglia. A slight degree of fatty metaplasia was evidenced by a single fat droplet in the cell body. More advanced fatty metaplasia was indicated by various-sized large fat droplets, most of which by far exceeded the original volume of the cell (Fig. 2). The cytoplasm of such cells was stretched to a thin spherical shell and the perikaryon was flattened, as in adipose cells. The fat droplets had been removed from some cells during cutting, and these cells appeared as empty, spherical vesicles (Fig. 2). It appeared that the amount of enzyme activity was in a crude inverse proportion to the fatty metaplasia in the cells. At early phases of fatty metaplasia, the enzyme activity in the cells was not visibly weaker than normal, but very little enzyme activity was present in the cells of fila with extreme fatty metaplasia.

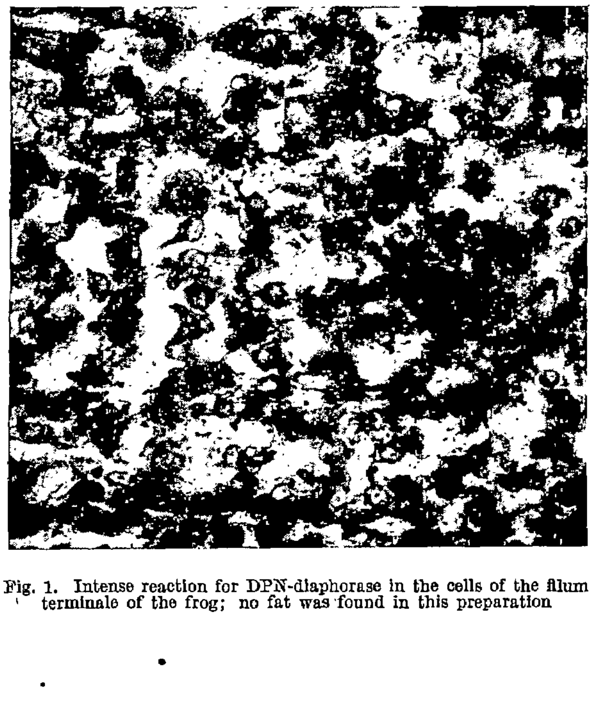

Fig. 1. Intense reaction for DPN-diaphorase in the cells of the filum terminale of the frog; no fat was found in this preparation

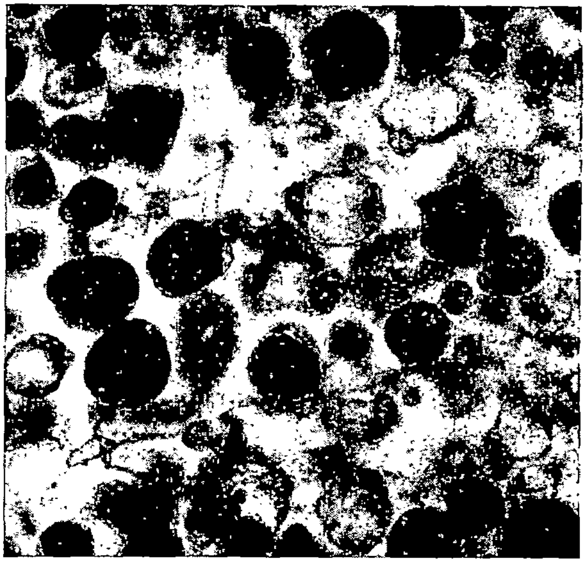

Fig. 2. Fatty metaplasia of filum terminale; DPN-diaphorase, counterstained with fat-red. The fat droplets had been removed from some of the cells, which show only an empty shell of cytoplasm, demonstrated by enzyme activity. In the original preparation, fat is bright-red and the enzyme reaction dark blue

These observations offer no clues as to the possible causes of this type of fatty metaplasia which seems to represent a physiological process in the filum terminale of the frog. The ability to store fat, much like adipose cells do, strikingly distinguishes the tissue of the filum of the frog from that of any other portion of the central nervous system. It seems quite clear that the filum terminale of the frog is not suitable for examination of glial metabolism.

PATHOLOGY

Effect of Colchicine on Human Tumours transplanted in Cheek Pouch of Syrian Hamster

THE human tumour transplanted in the cheek pouch of the Syrian hamster has proved to be a useful tool for the examination of potential anti-tumour agents[1,2]. What appears to be an obvious advantage in using transplantable human tumours over transplantable animal tumours in chemotherapy investigations lies in the fact that a given compound can be assayed on cells of human origin growing in an *in vivo* system. However, at least two conditions would have to be fulfilled prior to making such a comparison: (1) transplanted human tumours should not

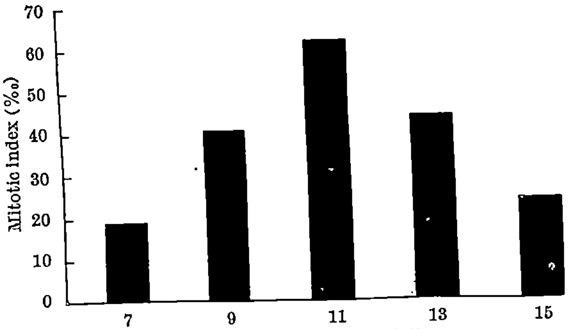

Fig. 1. Mitotic indices after colchicine (1·2 mg/kg) in *ME*-1 tumour growing in the cheek pouch of Syrian hamster

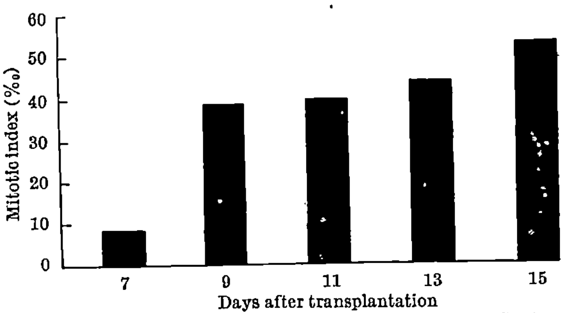

Fig. 2. Mitotic indices after colchicine (1·2 mg/kg) in *MFS*-1 tumour growing in the cheek pouch of Syrian hamster

undergo profound changes in their biological properties; (2) the host should not alter the effect of the tested agents on the human cells.

Heterologous transplantation studies of human tumours in hamsters, mice, and rats, by several investigators have revealed that very little alteration in the general histological appearance of human tumours occurs in the new host[2-5]. Furthermore, immunological studies conducted by Korngold[6,7] have demonstrated that human tumours transplanted in hamsters or rats retain, at least partially, their original antigenic constitution, even after undergoing repeated transplantations. It appears from these findings that no radical changes occur in transplanted human cells by serial passage in hamsters.

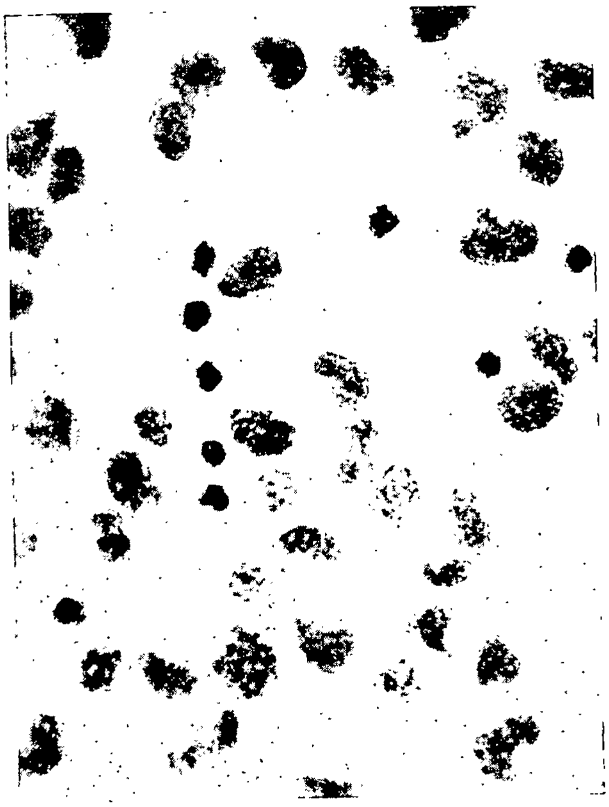

Fig. 3. Arrested metaphases, after colchicine treatment, in *ME*-1 tumour 11 days after transplantation. (Squash preparation, Feulgen; × 800)

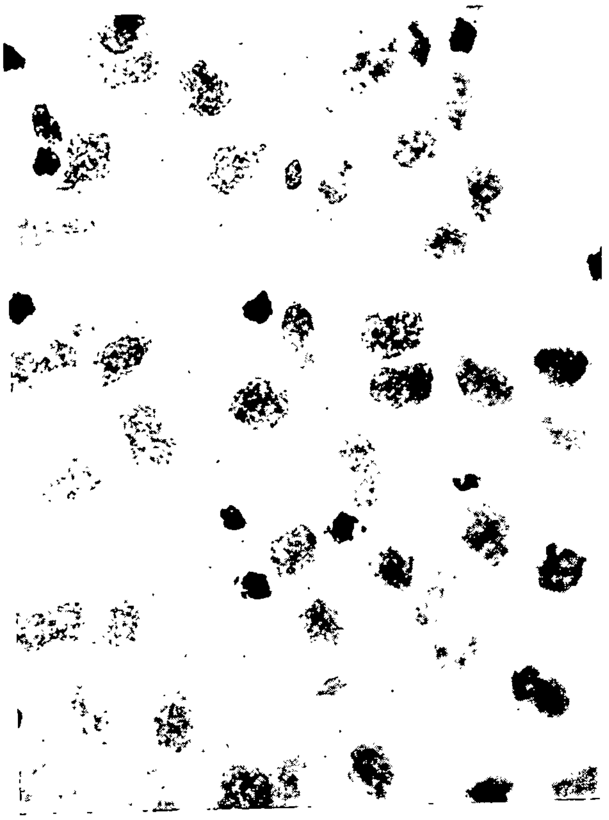

Fig. 4. Arrested metaphases, after colchicine treatment, in *MFS*-1 tumour 15 days after transplantation. (Squash preparation, Feulgen. × 800)

In evaluating the effect of a given compound on human cells transplanted in the hamster cheek pouch, consideration must be given to the influence of the new environment on the transplanted cells, and on the compound itself.

It has been known for some time that the Syrian hamster differs from other mammals in its sensitivity to the stathmokinetic effect of colchicine[8-11]. Orsini considered this animal to be completely resistant to the effect of this alkaloid[8]. In a recent investigation we have been able to demonstrate that the Syrian hamster is only partially resistant to the stathmokinetic effect of colchicine[11]. In fact, Syrian hamsters injected with a dose of 1·2 mg/kg colchicine, which is effective in causing metaphase arrest of dividing cells in other mammals, did not show any accumulation of arrested metaphases, while hamsters injected with 2·4 mg/kg or higher doses showed metaphase arrest in only some bone marrow dividing cells[11]. Midgley *et al.*[10] observed that colchicine induced metaphase arrest in human testicular tumours transplanted in the cheek pouch of Syrian hamsters, in spite of the resistance of the hamster to this alkaloid.

The purpose of the investigation reported here was to study the effect of colchicine on other human tumours transplantable in Syrian hamsters, and to investigate whether such tumours were sensitive to the effect of the alkaloid during all phases of growth.

Two human tumours, transplantable in the cheek pouch of the Syrian hamster, were used in these experiments: a myxofibrosarcoma (*MFS*-1) and an amelanotic melanoma (*ME*-1) (2). *MFS*-1 and *ME*-1 tumours were

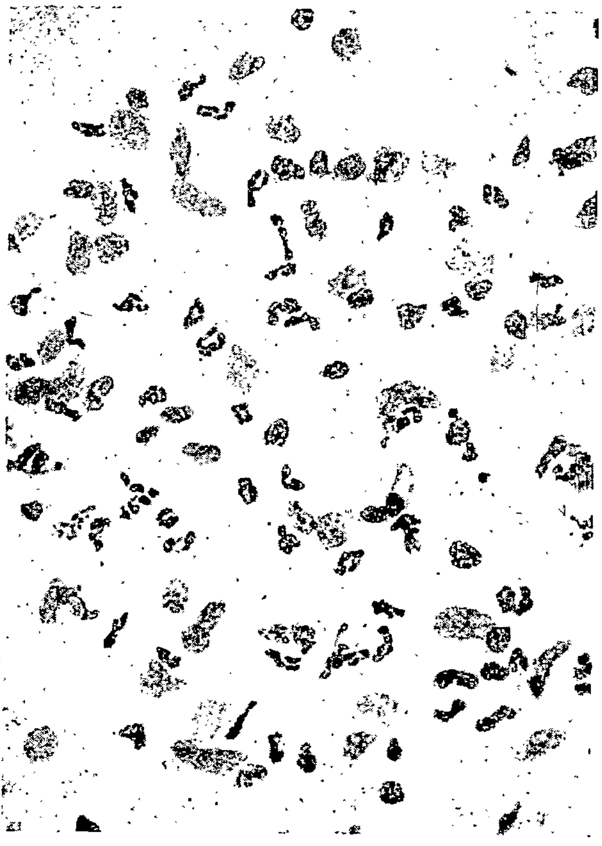

Fig. 5. Leucocytic infiltration in an *MFS*-1 tumour in regression. (Squash preparation, Feulgen; × 600)

transplanted into two groups of 40 hamsters each, 5–8 weeks of age, and of both sexes. The technique of transplanting tissues to hamster cheek pouches is described elsewhere[1,12]. On the fifth day following transplantation, hamsters bearing established tumour grafts were divided into groups of 5 animals each. At various time-intervals, starting from the seventh day after transplantation, a group of hamsters was killed 4 h after receiving, intraperitoneally, 1·2 mg/kg of colchicine. Immediately after death, the tumour was removed from the cheek pouch, minced with scissors, and fixed in 1 : 3 acetic/alcohol. Preparations for cytological study were made according to the Feulgen squash method. Mitotic indices were determined by counting at least 2,000 cells on each preparation.

In earlier experiments, it was observed that on the fifth day after transplantation, only a very few mitoses were present in the tumours; therefore, mitotic indices were determined at various time intervals from the seventh to the fifteenth day after transplant. In both *ME*-1 and *MFS*-1 tumours, arrested metaphases were observed on the seventh day after transplantation. The number of arrested metaphases increased progressively in the following days, reaching the maximum on the eleventh day in *ME*-1, and the fifteenth day on *MFS*-1 (Figs. 1, 2, 3, and 4). Post-metaphase figures were practically absent in almost all preparations. The progressive increase of the mitotic index paralleled pretty well the increase in size of the tumours. Some of the tumours which, after initial growth, showed a tendency to regress were also studied. These showed a large number of degenerating cells and extensive leucocytic infiltration. Mitotic figures in these tumours were always rare, or very low in number (Fig. 5).

Results obtained in this investigation indicate that human tumours growing in the cheek pouch of the hamster are fully sensitive to the stathmokinetic effect of colchicine during the entire period of growth.

Tumour sensitivity exists in spite of repeated serial transplantation in the hamster. The experimental evidence presented herein provides further strength for considering the hamster–human tumour system as a tool for assaying compounds as potential anti-tumour agents in man. Whether the hamster–human tumour system will indeed prove more suitable as a method for demonstrating human anti-tumour activity than the other systems currently in use will await clinical trial and evaluation.

This investigation was supported in part by research grants from the National Cancer Institute, National Institutes of Health, U.S. Public Health Service, Nos. *CY*-3335 and *C*-6516.

Proliferation and Maturation Defect in Acute Leukæmia Cells

PREVIOUS *in vitro* investigations have shown that thymidine incorporation in acute leukæmia cells is very low compared with that in hæmocytoblasts and myeloblasts of normal bone marrow or in chronic myeloid leukæmia[1–3]. This was taken to be a sign of reduced proliferative capacity in acute leukæmia cells, in accordance with stathmokinetic investigations of Astaldi and Mauri[4]. Lajtha and Craddock also noted a low degree of tritiated thymidine incorporation in acute leukæmia cells[5,6] and, by direct *in vivo* precursor administration Mauer and Fisher[7] and Killman *et al.*[8] were able to obtain direct evidence of the prolonged generation time of these cells.

Further *in vitro* and *in vivo* work has been undertaken to define more exactly the extent and significance of the phenomenon. For this purpose it was decided to: (1) establish whether or not the defect in proliferative capacity of acute leukæmia cells is related in some way to another defect long recognized as characteristic of these cells, namely, an absolute inability to mature; (2) define the significance of blast cell population heterogeneity, if any, in connexion with reduced proliferative capacity. To achieve the first objective we extended our investigations to intermediate clinical conditions, such as the terminal myeloblastic crisis of chronic myeloblastic leukæmia and the remission phases of acute leukæmia. For the second objective it was necessary to divide the cell population of each case into different classes according to cell diameter, so that proliferative capacity could be evaluated for each class.

In vitro investigations were conducted on 22 cases of acute leukæmia, 11 cases of chronic myeloid leukæmia, 7 cases of chronic myeloid leukæmia in various stages of terminal blastic crisis and 2 cases of acute leukæmia exhibiting a hæmatological remission after a complete course of 6-mercaptopurine therapy. The technique has

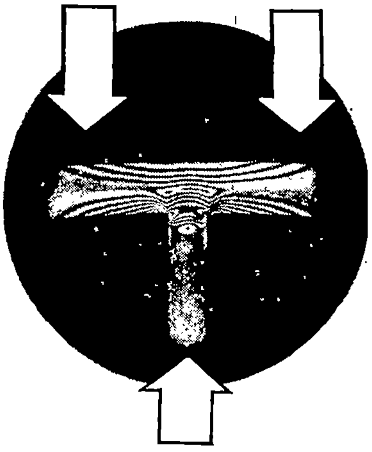
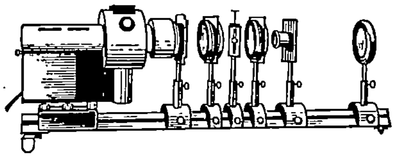
REVEALING THE EFFECTS OF

⬅ STRESS ➡



IMPORTANT APPLICATIONS OF SPINDLER & HOYER OPTICAL BENCHES



Beam of light from carbon arc lamp is gathered in optical condensers, transmitted through polarizing screen, specimen, analysing screen and objective, which projects it on viewing screen. Spindler & Hoyer optical benches feature an automatic feeding device to move carbons uniformly through the lamp and eliminate adjustment. A wide range of sliding carriages and other accessories makes them extremely versatile.

(2) TEACHING

When specimens of plastic or special glass are fitted to a Spindler & Hoyer optical bench and subjected to stress, an image showing the effects is projected for observation. It may be filmed or photographed as a record. The instrument provides lecturers with a particularly graphic means of illustrating the principles of mechanics at work.

Industrial applications are numerous—Spindler & Hoyer optical benches are valued as time and money-saving equipment in many leading laboratories. For example, they are used to test glass and plastic mixes and product designs before manufacture, and to investigate the effects of stress on engineering projects at the technical design stage. PARTICLE PROBLEMS OR...
PROBLEM PARTICLES

IT COULD SAVE YOU

a lot of time and trouble if particle size analysis is part of the job.

Particle size and size distribution is becoming of increasing importance in every form of industry, affecting such diverse characteristics of the finished product as strength, texture, efficiency, taste, adhesion, etc. No longer need you be the slave of laborious, time-consuming sedimentation and microscopic methods. With the Coulter Counter particle size analysis from 0.3 micron upwards can be undertaken rapidly and simply by relatively junior staff. Speed and accuracy of counting is such that it can be used not only for pure and applied research but also for "on-stream" quality control, and the detection of small numbers of over-size particles.

If you have particle problems or are plagued by problem particles, why not write to us for literature showing how the Coulter Counter can help?

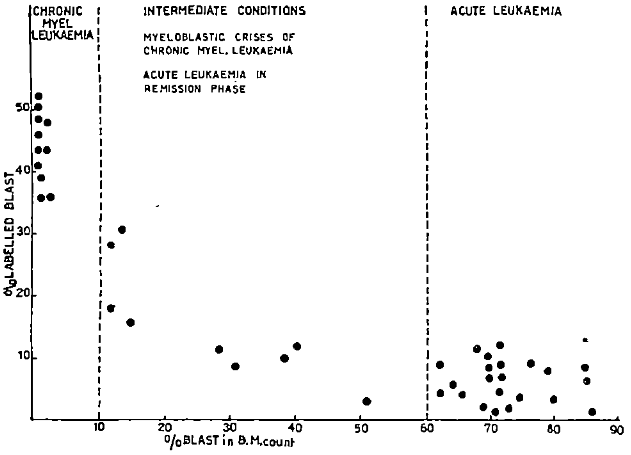

Fig. 1. Correlation between percentage of blasts and labelling index in the different leukæmia conditions

already been reported[3]. For the *in vivo* investigation, 0·15 mc./kg of tritiated thymidine (specific activity 1·4 c./m.mole) was injected intravenously into the acute leukæmia patients and peripheral blood samples drawn at various intervals for 4 days.

Fig. 1 shows the percentage of thymidine-labelled blast cells (or labelling index) of, respectively, chronic myeloid leukæmia, intermediate conditions and acute leukæmia. If the labelling index is correlated with the percentage of blast cells in bone marrow smears it is clear that the higher the percentage of blasts the lower their proliferative capacity. This is clearly seen in the individual cases of chronic myeloblastic leukæmia in which the course of the disease could be followed closely up to the terminal myeloblastic crisis. The phenomenon was also observed during hæmatological remission in a case of acute leukæmia.

In 4 cases of acute leukæmia and in 1 case of blastic crisis studied *in vitro* and in the 2 cases of acute leukæmia examined *in vivo* the blast cell population was divided into different classes according to cell diameter. Heterogeneity was evident in all cases, with larger blast cells containing a great number of nucleoli at one extreme and much smaller cells with few nucleoli (and often a lesser degree of cytoplasmic basophilia) at the other. The percentage degree of tritiated thymidine incorporation was determined for each class. Incorporation was highly heterogeneous between the different classes, those with greater cell diameter giving values of normal or chronic myeloid leukæmia cells (Table 1). It should be borne in mind that a higher labelling index in larger cells may be due simply to the fact that cell diameter increases during the *S*-period[9]. An examination of blast cells of normal bone marrow (a homogeneous cell population) gave a mean diameter ratio of labelled to non-labelled blasts of 1·1. Since the differences in incorporation between the various classes of leukæmia cells are of the order of 20- to 30-fold we may dismiss this factor of increasing cell diameter as having no appreciable effect on the findings of our investigation.

Hale and Cooper recently reported an increased rate of DNA synthesis in larger blasts[10].

b.m., bone marrow; p.b., peripheral blood.
* *In vivo* experiment. † Blastic crisis of chronic myeloid leukæmia.

In two untreated cases of acute leukæmia, tritiated thymidine was injected *in vivo*. Intravenous tritiated thymidine administration is known to correspond to a pulse-labelling process[11]: for about 20 min the precursor is incorporated in all the cells which are in the phase of DNA synthesis. Thereafter, up to the ninety-sixth hour, the labelling index was evaluated on peripheral blood in each of the cell-diameter classes. In both cases the behaviour of the labelling index differed markedly according to the different classes. Fig. 2 illustrates the situation in one case (F. S.); that in the second case (C. B.) is very similar. In the larger cell-diameter classes the labelling index (initially very high) fell rapidly during the first 24 h; in the smaller cell-diameter classes the labelling index rose gradually from very low values (1–3 per cent) to high values (10–20 per cent).

Comparative studies on cases of acute leukæmia, intermediate forms of the disease and chronic myeloid leukæmia point decisively to a link between the gradual increase in blast cell population and the fall in average proliferative capacity. However, a gradual percentage increase in the blast cell population also implies the appearance and progressive intensification of a maturation defect. Consequently, it is reasonable to assume that the existence of a maturation defect is connected with that of a proliferation defect.

Is there a causal link between the proliferation defect and the maturation defect, both of which characterize and define every picture of acute leukæmia ? An affirmative answer to this question is suggested by the findings of our second series of investigations, which provided evidence of different cell classes with strikingly different percentage degrees of thymidine incorporation both in acute leukæmia cell populations and in those of leukæmia in blastic crisis. Labelling indices ranged from near-normal or chronic leukæmia values to extremely low values. *In vivo* investigations undertaken to examine the fate of the various classes of thymidine-labelled cells have shown clearly that in a single population the larger cells are generally the less aged and that over subsequent divisions (altogether ineffective as regards maturation) these cells gradually become smaller in diameter, thereby swelling the ranks of the smaller cell-diameter classes. In both cases the significance of the finding was beyond question. Clearly, then, the reduction in proliferative capacity observed in leukæmia cell populations is not a homogeneous phenomenon: the values obtained from the population as a whole are simply the mean values between the younger blast cells still in possession of a high proliferative capacity and the older blast cells which have

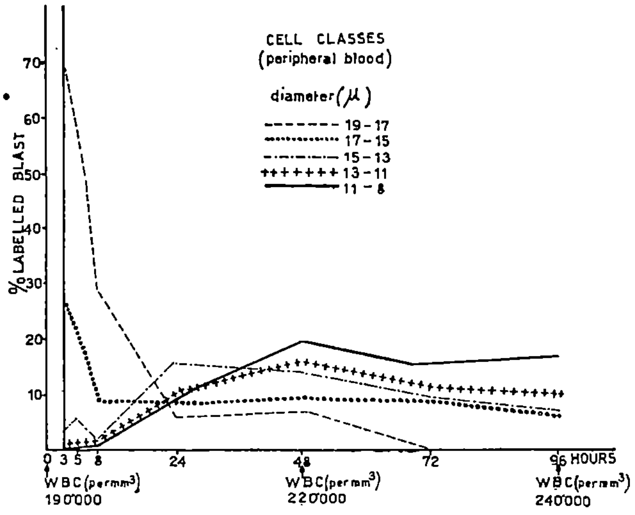

Fig. 2. (Patient F. S.). Tritiated thymidine labelling index in the different blast cell classes of peripheral blood after the intravenous administration of 0·15 mc/kg precursor

gradually lost their proliferative capacity. In other words, the ageing of a population of blast cells lacking the capacity of differentiation involves the progressive loss of their proliferative capacity. Young blast cells are found in greater numbers in bone marrow than in peripheral blood. This explains the differences in the mean proliferative capacity revealed by simultaneous analysis (Table 1)[12].

In conclusion, the foregoing findings provide a basis for the postulation of a unitary theory on acute leukæmia. In this disease there is only one major functional cell defect, namely, an absolute incapacity for differentiation and maturation. As the cells grow older without maturing they gradually lose their proliferative capacity. The existence of this defect in acute leukæmia cells or its development during the blastic crisis in chronic cases probably indicates the existence or development of new lines of blast cells which have lost nuclear control over differentiation, so that the genetic information governing the synthesis of specific proteins is lost, inhibited or suppressed. As pointed out in a previous communication[1], this concept of acute leukæmia suggests the need for developing new lines of approach to the rational treatment of the disease.

BIOLOGY

A Haploid Tissue Culture from the Female Gametophyte of *Ginkgo biloba* L.

Haploid tissue cultures of the female gametophyte of *Ginkgo biloba* L. have been obtained successfully for the first time. The tissues are green, show a considerable degree of differentiation, and grow well on a chemically defined medium.

The female gametophyte tissue is located in the seeds, and it develops in a definite pattern over a period of four months[1]. It goes through a free nuclear stage, segmentation, growth, archegonia formation, and finally, after fertilization, it matures as storage parenchyma. In its mature form it serves as food for the germinating embryo[2].

After investigating the female gametophyte for several years using a variety of media, it was found that the stage of development best suited for growth *in vitro* was that occurring at 11–13 weeks after pollination, that is, during growth and the formation of archegonia, but before fertilization and maturation took place. At this stage, the gametophyte tissue consisted of a green, egg-shaped structure about 10–15 mm in size surrounded by the hard and fleshy seed coats. The intact seeds were surface sterilized in a 1 per cent hypochlorite solution, washed in sterile water and then dissected on sterile paper towelling. The seed was bisected at right angles to th median longitudinal axis; this divided the female gamet phyte into equal halves: an apical (archegonial) half an a basal (non-archegonial) half. The seed coats an nucellus were removed, and the apical and basal portion of the gametophyte grown in separate test tubes. Sinc it was known that archegonia sometimes occurred dis placed from the apical region[1], the two halves wer cultured separately to reduce the possibility of archegoni tissue being included in the basal end. An examination the neck canal cells of the archegonia in the apical end showed these cells to be turgid. This was evidence tha fertilization had not occurred. Moreover, fertilization wa very unlikely to have occurred, since it normally too place 17–19 weeks after pollination, whereas excision wa carried out at 11–13 weeks.

The apical and basal halves of the female gametophyt were initially cultured on White's medium[3] supplemente with 6 p.p.m. 2,4-dichlorophenoxyacetic acid (2,4-D) an 18 per cent coconut water (v/v). On this medium th gametophyte proliferated at the junction of the tissue an medium; the apical tissue also formed tissue outgrowth in the area surrounding the archegonia. After severa sub-cultures on this medium, the tissue masses wer removed and transferred to a medium with the followin conposition (mg/l.): KCl, 900; KNO_3, 80; $MgSO_4 \cdot 7H_2O$ 760; $NaNO_3$, 1,800; $Ca(NO_3)_2 \cdot 4H_2O$, 280; $NaH_2PO_4 \cdot H_2O$ 300; Na_2SO_4, 200; KI, 0·5; H_3BO_3, 0·2; $MnSO_4 \cdot H_2O$, 0·8 $ZnSO_4 \cdot 7H_2O$, 0·5; $CuSO_4 \cdot H_2O$, 0·02; MoO_3, 0·01; $CoCl_2$ $6H_2O$, 0·01; ferric citrate, 5·0; calcium pantothenate, 1·0 pyridoxine·HCl, 0·5; thiamine·HCl, 0·5; nicotinic acid, 1·0 sorbitol, 100; adenine, 10·0; kinetin, 0·5; naphthalene acetic acid. 1·0; sucrose, 20,000; agar, 10,000; glutamine 200; *m*-inositol, 100; cytidylic acid, 100; guanylic acid 100. The last four components were filter-sterilized an the *p*H of the medium was adjusted to 5·5. This mediu was based in part on one used by Wood and Braun fo *Vinca* tissue cultures[4], but was modified with respect t the trace elements, vitamins, sorbitol, and adenine. Not all the constituents of this medium are known to b required for growth, hence this is not considered a minimal medium. The tissue has been maintained on this mediu by transferring at monthly intervals for more than a year.

Later experiments indicate that the synthetic medium is adequate for starting the tissue cultures, but that the medium containing coconut water and 2,4-D is better. Once good growth is initiated (after 2–3 months) the synthetic medium is better for continued proliferation o the tissue. The tissue is friable when young but becomes harder and more compact as it ages. Microscopic examination shows a fairly abundant development of tracheid-like cells in the interior of tissue masses; chloroplasts are conspicuous in the younger cells. Chromosome counts show 12 chromosomes and confirm the haploid origin of the tissue.

Newcomer[5] reported the parthenocarpic development of *Ginkgo* seeds and Favre-Duchartre[1] reported on the abnormalities and the *in vitro* culture of the female gametophyte; but neither paper mentioned the development of a tissue or organs. Favre-Duchartre did observe some cellular growth and divisions in his cultures, but no tissue formation, continued growth, or organ development. In the cycads, however, apospory was described by Duchartre[6]; he noted the spontaneous formation of roots from the female gametophyte of *Cycas thourarsii.* LaRue[7] noted the development of both roots and shoots on gametophytes of *Zamia floridana* and *Cycas revoluta*; he grew gametophytes for more than a year on culture media of sterile sand or coconut water and obtained whole plants. However, LaRue reported no tissue cultures from these plants.

Tissue cultures have been obtained from the male gametophyte (pollen) of *Ginkgo biloba* L.[8]. These tissues are haploid and are made up of white, undifferentiated parenchyma cells which are derived from meristematic centres and may be cultured continuously on a defined medium[9]. Thus, it is believed that this is the first case where tissue cultures of both the male and the female gametophytes of a higher plant have been grown *in vitro*.

As a diœcious species, *Ginkgo* shows no phenotypic sex differences except in the production of male or female strobili. Hence, it is presumed that the genomes of the two haploid tissue cultures derived from the gametophytes of the male and female trees are identical in all respects except for sex-linked characters. The gross differences seen *in vitro* are the white, undifferentiated character of the male tissue and the green, differentiated character of the female tissue. Recent chromosome counts of both tissues show a basic haploid number of twelve, but nothing is known of the karyotype of the tissues. Previous reports[10,11] indicated the presence of a sex-linked satellite, but more recent investigations[12] did not confirm these findings.

It is suggested that the two haploid gametophyte tissues of *Ginkgo* provide an experimental system which may be useful for work on experimentally controlled regeneration, for investigations on the genetic and biochemical basis of sexual differences in higher plants, and perhaps for examination of conditions which affect chloroplast formation. In addition, the female gametophyte of *Ginkgo* is known to have growth-promoting properties similar to those found in coconut water, corn endosperm and *Aesculus* endosperm[13]; the tissue culture from the gametophyte may be useful in studying the nature of these substances. It has also been shown by Yih and Clark[14] that the male gametophyte tissue of *Ginkgo* has a boron requirement; it will be of interest to see whether the analogous green tissue of the female gametophyte of *Ginkgo* also has this requirement, in which case both tissues may be useful in examining the role of boron in cellular metabolism.

Cytoplasmic Inheritance in Amœbæ: Nuclear Transfer Investigations

INVESTIGATIONS into the molecular basis of cytoplasmic inheritance in the large, uninucleate amœbæ, *Amoeba proteus* and *Amoeba discoides*, have shown that certain self-replicating cytoplasmically inherited determinants can be transferred from one strain to the other, by the micro-injection of relatively small quantities of non-homologous cytoplasm[1,2].

In addition to characters determined by nuclear factors, *A. proteus*, ${}_{T1}P$ differs from *A. discoides*, ${}_{T1}D$ in several cytoplasmically influenced characters. Two characters selected as experimental markers were mean nuclear diameter[3] and streptomycin sensitivity[4]; ${}_{T1}P$ having a higher mean nuclear diameter and greater streptomycin sensitivity.

After the injection of relatively small quantities of ${}_{T1}D$ cytoplasm into whole ${}_{T1}P$ amœbæ, 25 per cent of the receptor cells survived and formed flourishing mass cultures. Of these clones, approximately 20 per cent show decreased mean nuclear diameter and decreased streptomycin sensitivity. In normal amœbæ mean nuclear diameter and level of streptomycin sensitivity are not associated. Some indication of the degree of assimilation, and presumably replication, of the foreign cytoplasm in these clones could be obtained by transferring nuclei from 'parent' clones into injected cell lines and vice versa.

In addition, these clones of 'injected' amœbæ offered another means of investigating the incompatibility that exists between nucleus and cytoplasm of different strains, which is similar to that met with in transplantation experiments with other organisms, for example, *Stentor*[5] or *Amphibia*[6]. Thus when ${}_{T1}D$ nuclei are transferred into the enucleate cytoplasm of ${}_{T1}P$, the cytoplasm may be re-activated and divide several times, but a viable clone is very rarely obtained. Homotransfers, transfers between nuclei and cytoplasms of the same strain, that is, ${}_{T1}P_n \longrightarrow {}_{T1}P_c$, are at least 90 per cent successful and give flourishing mass cultures.

The viability of nuclei and the state of the cytoplasm of one of the 'injected' clones, namely, one obtained from ${}_{T1}P$ injected with ${}_{T1}D$ cytoplasm which was apparently assimilated, as judged by decrease in mean nuclear diameter and decreased streptomycin sensitivity, were investigated. Using the technique of nuclear transfer[7], experiments were carried out in order to ascertain:

(*a*) the viability of ${}_{T1}D$ nuclei in the cytoplasm of the clone obtained from the injected cell, $({}_{T1}D_c \dashrightarrow {}_{T1}P)_c$; (*b*) the viability of ${}_{T1}P$ nuclei in the cytoplasm of the clone obtained from the injected cell $({}_{T1}D_c \dashrightarrow {}_{T1}P)_c$; (*c*) the viability of nuclei from the 'injected' clone $({}_{T1}D_c \dashrightarrow {}_{T1}P)_n$ in ${}_{T1}P$ cytoplasm; (*d*) the viability of nuclei from the 'injected' clone $({}_{T1}D_c \dashrightarrow {}_{T1}P)_n$ in ${}_{T1}D$ cytoplasm.

These experiments were carried out on amœbæ separated by at least 50 cell divisions from the original injected cell, and the results obtained are given in Table 1.

Table 1

Type of transfer	Transfer	Expected percentage of clones	Actual percentage of clones obtained
Homotransfer	${}_{T1}P_n \longrightarrow {}_{T1}P_c$	100	90
Homotransfer	${}_{T1}D_n \longrightarrow {}_{T1}D_c$	100	90
Heterotransfer	${}_{T1}P_n \longrightarrow {}_{T1}D_c$	< 5	< 1
Heterotransfer	${}_{T1}D_n \longrightarrow {}_{T1}P_c$	< 5	< 1
Transfer into 'injected' clone	${}_{T1}D_n \longrightarrow ({}_{T1}D_c \dashrightarrow {}_{T1}P)_c$	< 5	48
Transfer into 'injected' clone	${}_{T1}P_n \longrightarrow ({}_{T1}D_c \dashrightarrow {}_{T1}P_c$	100	0
'Injected' clone nuclei	$({}_{T1}D_c \dashrightarrow {}_{T1}P)_n \longrightarrow {}_{T1}P_c$	100	0
'Injected' clone nuclei	$({}_{T1}D_c \dashrightarrow {}_{T1}P)_n \longrightarrow {}_{T1}D_c$	< 5	0*

$\rightarrow$ Nuclear transfer. $\dashrightarrow$ Injection of cytoplasm.

Results of transfer experiments using a clone of *A. proteus* which had received and assimilated an injection of *A. discoides* cytoplasm, compared with results obtained from homotransfer and heterotransfer experiments.

From these results it was apparent that ${}_{T1}P$ nuclei were no longer viable in the cytoplasm of the 'injected' cells (that is, *A. proteus* which had received and presumably assimilated an injection of *A. discoides* cytoplasm), while the considerably increased percentage of viable clones obtained from the transfer of ${}_{T1}D$ nuclei into these cells indicated the extent of the change in these formerly 'proteus' amœbæ. The nuclei of the 'injected' clone were no longer viable in ${}_{T1}P$ cytoplasm, neither were they viable in ${}_{T1}D$ cytoplasm, although in the latter experiments many transfers divided to give 30 or more cells before death. The behaviour of 'injected' amœbæ in these nuclear transfer experiments is a further indication of the successful assimilation of non-homologous cytoplasm.

Nuclear transfers between more widely separated species, for example, *A. dubia* and *A. proteus*, have proved unsuccessful so far[8]. Prior injection of non-homologous cytoplasm and its successful assimilation, even in a very low percentage of cells, would be a means of obtaining clones of a mixed type able to accept foreign nuclei. Experiments of this type are in progress.

This work was supported by grants from the Royal Society.

Moulting Frequency of a Deep-sea Crustacean, *Euphausia pacifica*

Most of the observations on moulting in crustaceans have been confined to littoral animals kept in aquaria[1]. Because planktonic, deep-sea crustaceans are difficult to maintain in the laboratory there has been virtually no information available on moulting frequency in these forms. In connexion with experiments designed to determine filtering rates and the quantitative aspects of carbon metabolism in the deep-sea planktonic euphausiid shrimp, *Euphausia pacifica*[2], observations were made on the moults and moulting frequency of this animal.

E. pacifica is an important and ubiquitous component of the deep-sea plankton in a broad oceanic region ranging from the north of Japan across the Bering Sea to Baja, California, Mexico[3]. In the laboratory *E. pacifica* has been kept alive for more than 7 weeks on a diet of the green flagellate *Dunaliella primolecta* and/or *Platymonas subcordiformis*.

Each animal, ranging in dry weight from 1·2 to 4·8 mg, was kept in 1 l. of sea water and the water changed every three days. One drop of algal suspension was added daily, but no attempt was made to determine how much food was actually ingested by the euphausiids. All containers were examined daily for cast moults. Recovered moults were rinsed in distilled water, dried at 80° C on a microscope slide and weighed with a Cahn electrobalance to ± 0·002 mg. Temperature was not rigidly regulated but normally held within narrow limits. Only those animals which had moulted more than once are included in this work.

The results summarized in Table 1 show that within the range of experimental temperatures (9°–14° C) the moulting frequency was 5 days with a standard deviation of o day (range 4–7 days). Each cast moult averaged 10 cent of the animal's dry weight. There is no appare correlation of moulting frequency with temperature or a of the animal, although it is quite likely that furcilia a calyptosis stages have more frequent moults as do mo developing crustaceans[1]. Temperature may have had small effect, but because observations were made daily a not hourly these may have been masked.

Table 1. Moulting Frequency of *Euphausia pacifica*
(*S.D.*, standard deviation)

Euphausiid	Temperature range	Final animal dry weight (mg)	No. of moults produced	Average weight moult	Time (days) alive in laboratory	Average moulting frequency (days)	Moults = percentage of animal dry weight

19	15·4–18·9	1·326	8	0·121	40	5	9·1
						Av. 5 ± 1 (*S.D.*)	Av. 10·4 ± 2·4 (*S.D.*)

One animal lived 50 days in the laboratory and h passed through 11 moults, while another of similar si (1·3 mg) went through 10 moults in 36 days. Ash weigh averaged 54·4 per cent of the moult dry weight (range f four determinations 52·9–56·9 per cent) and the organ components 45·6 per cent by difference. Nitrogen w 1·5–2·5 per cent of the moult dry weight or between 3 an 5 per cent of the ash-free moult dry weight.

There are large populations of euphausiid shrim throughout the deep oceans. If moulting occurs in th sea as frequently as it has been observed in the laborator the moults represent a tremendous amount of organ material added daily to the rain of materials known a detritus in the sea. For example, each euphausiid con tributes its full body-weight in cast moults every 50 day The importance of organic detritus in the sea was discusse by Parsons and Strickland[4]. The results presented her show that the moults of planktonic crustaceans coul contribute a substantial portion of this material.

Body Temperature of Yellowfin and Skipjack Tunas in Relation to Sea Surface Temperature

Tunas are frequently cited as the exception to the generality that fishes are poikilothermic. These references to temperatures higher in tunas than in their environment are mainly based on measurements made with mercury thermometers on isolated specimens at one or two sea temperatures[1], circumstances which result in less-than-accurate temperature measurements, and which fail to describe adequately the body temperature–sea temperature relation over the thermal range of the tunas. The single report[2] of tuna body temperatures over a wide range of sea temperatures is based on measurements made with the mercury thermometer.

In the course of other investigations, we had the opportunity of measuring, with thermoelectric techniques, the

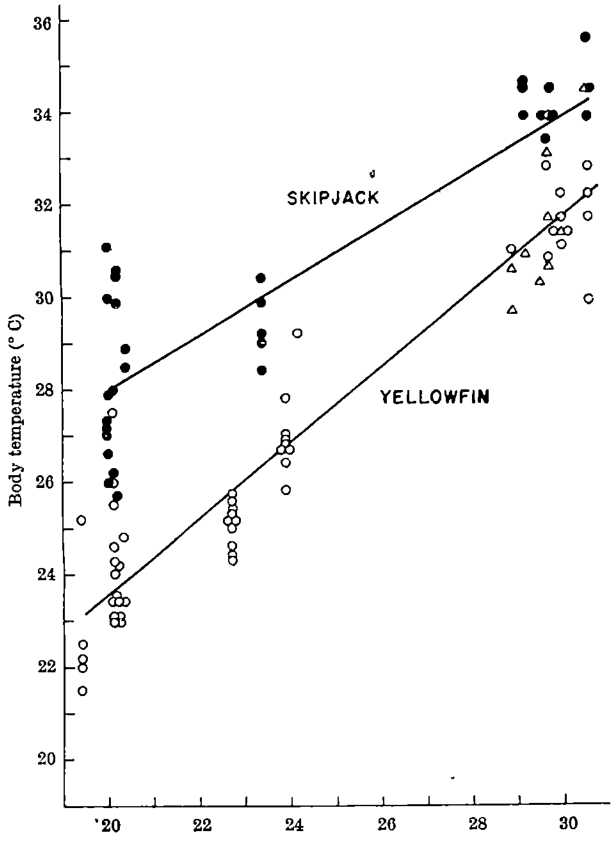

Fig. 1. Relation of body temperature to sea surface temperature. ●, Skipjack; ○, yellowfin; △, yellowfin in sea

deep-muscle temperatures of 62 live yellowfin tuna (*Thunnus albacares*) (length-range, 530–882 mm) and 31 live skipjack tuna (*Katsuwonus pelamis*) (length-range, 467–555 mm) captured in the eastern tropical Pacific Ocean, at sea temperatures of 19·4°–30·6° C. Body temperatures were measured with either the *YSI* model 47 telethermometer or the Electrotemp remote reading thermometer, both calibrated against standard mercury thermometers. The thermistor probes were inserted deeply into the lateral muscles, midway between the origins of the dorsal and pectoral fins. Most readings were taken on live fish within 1 min after being brought on deck, after capture by live bait methods[3], by purse-seine, or by trolling; the remainder were made on hooked yellowfin swimming in the sea at the end of a line.

The plot of these results (Fig. 1) shows the linear least squares regression of body temperature of each species on the temperature of the environment at the time of capture. The equations are:

$$\begin{aligned}&\text{yellowfin body temperature °C} = 0{\cdot}81 \text{ water temperature °C} + 7{\cdot}47\\ \text{and } &\text{skipjack body temperature °C} = 0{\cdot}58 \text{ water temperature °C} + 16{\cdot}39\end{aligned}$$

The regression lines are significantly different in both slope and level. The correlation coefficients are 0·95 and 0·87 for the yellowfin and skipjack, respectively.

Over the size range of the fish tested, length was of minor importance in the body temperature–sea temperature relation for the yellowfin (body temperature °C = 6·49 + 0·86 water temperature °C–0·0002 body length mm, for the 53 fish for which length measurements were available). In the skipjack, however, the small fish tended to have lower body temperatures than did the large (body temperature °C = 8·63 + 0·59 water temperature °C + 0·015 body length mm).

Although the effects of stimulation, handling, heat gradients within the fish, and fish size must be considered in assessing these results, the similarity of the temperatures of yellowfin in the sea (Fig. 1, triangles) to those of yellowfin on deck immediately after capture (Fig. 1, open circles) suggests that the line for the yellowfin is valid. No such confirmatory results are available for the skipjack, but there is little reason for suspecting the validity of the line.

Examination of blood hæmoglobin-levels[4], muscle glycogen content[5], blood lactate accumulation[6], and mortalities after handling[6] and tagging[7] in both the yellowfin and skipjack indicates that these two species live at a higher physiological rate than do other fishes which have been examined, the skipjack more so than the yellowfin[5–7]. The temperature results given here offer confirmatory evidence of this.

Another Giant Enteropneust from the Atlantic

THE largest known hemichordate is *Balanoglossus gigas* Fr. Müller. First discovered on the Atlantic coast of South America[1], this member of the family Ptychoderidae was found afterwards in considerable numbers at São Sebastião, São Paulo, Brazil[2]. Spengel[3] estimated its maximum length as 2·5 m, but specimens collected recently[4], although presumably complete, have not exceeded 2·3 m. The majority of the larger enteropneusts belong to this family.

Recently, March 1962, and again on the Atlantic coast of South America, at Praia do Araça, São Sebastião, Brazil, yet another giant enteropneust has been discovered. Unfortunately, the extreme fragility of the post-branchial region, especially when gorged with sand, has made it impossible to remove a complete specimen from its burrow. The largest and almost complete specimen obtained was 1·6 m long. A fully grown and fully extended specimen may well attain a length of 2 m, or even more.

Preliminary investigations show that this is a new species and a member of the family Spengelidae. By comparison the spengelids are only moderately large animals, although *Glandiceps talaboti* (Marion), also found in the Atlantic, may exceed half a metre in length[5]. It is remarkable that the two largest known enteropneusts have been found at Praia do Araça. This shore is also sparsely populated by *Balanoglossus clavigerus* Delle Chiaje. All three populations overlap one another and are confined to a region of the shore where the substratum remains saturated throughout the ebb-tide—a requirement common to many enteropneusts[6,7].

This is the first record of a spengelid from the South American coast, although *Tornaria* larvæ comparable to *Tornaria dubia* Spengel have been recorded off the coast of Brazil[8]. According to Stiasny-Wynhoff and Stiasny[9] *T. dubia* are the larvæ of *Glandiceps talaboti*, and in consequence Björnberg[8] suggests that this spengelid may turn up on the Brazilian coast. It also seems probable that these *dubia*-like *Tornaria* may prove to be the larvæ of the new spengelid species. Of the four specimens collected during March to August, one was a ripe female which released several hundred ova in an aquarium some hours after collection.

It is also another record of a spengelid inhabiting the same shore with more than one species of ptychoderid[10,11]. The remainder of the associated fauna included a large population of the lamellibranch *Anomalocardium brasiliana* Gmelin, the gastropod *Olivella verreauxi* Ducros, some burrowing decapod crustacea, a variety of small errant polychætes primarily *Ammotrypane aulogaster* Rathke, *Arenicola* sp., and numbers of very large *Eunice rousseaui* Quatrefages, commonly more than 1 m in length. This giant polychæte and the new spengelid lived at a slightly higher level on the shore than the *Balanoglossus gigas*.

The presence of a deep median dorsal sulcus on the proboscis, a small rudiment of a vermiform appendix on the buccal diverticulum and of peribuccal spaces, coupled with the absence of hepatic sacculations, lateral trunk septa and of synapticulæ, justify the identification of this spengelid as a new species of the little-known genus *Willeyia* Punnett 1906. This genus was first established by Punnett[12], who described *Willeyia bisulcata* from fragments of two specimens collected at Zanzibar, where it is said to be abundant. His description was not very accurate or as extensive as it might have been, and so doubt existed concerning the validity of the genus, until Horst[5] described *W. delagoensis* from a fragment of a single specimen collected at Inyack Island. This new discovery of several specimens in Brazil now makes it possible for us to corroborate Horst's observations and establish beyond doubt the validity of the genus *Willeyia*.

Little is known about the burrowing habits of the Spengelidae. The related genera *Glandiceps* and *Spengelia* are thought not to make permanent burrows. The new *Willeyia* species formed coiled casts on the surface, which were easily confused with those voided by the *Arenicola* sp. common in the same area. The burrows descended vertically from the cast to a depth of 30–35 cm before turning and following a long sinuous course at 50–70 cm below the surface. One burrow penetrated to a depth of 80 cm. They appeared to be devoid of any well-defined lining. No entrance holes were discovered.

Significance of Clutch-size in Swift and Grouse

WYNNE-EDWARDS[1] has so misunderstood the problem of clutch-size in the swift *Apus apus* at Oxford reported by Perrins[2] that further clarification seems desirable. First, he confused clutch-size (number of eggs laid) with brood-size (number of young at hatching). This is important because we often manipulated brood-size in the tower, as Perrins stated for broods of four, while most broods of one were due either to our manipulation or to hatching failures. Wynne-Edwards was, therefore, wrong in stating that clutches of four have been commoner in recent years, and that clutches of one, two and three have been in the proportion of 24 : 61 : 15. The swifts at Oxford have normally laid either two or three eggs, and natural clutches of one and four have been extremely rare.

The most critical question is what restricts the clutch to three, and Perrins's experiments, far too lightly dismissed by Wynne-Edwards, show that pairs with broods of four raised, on the average, fewer young than those with broods of three. In these circumstances, any tendency to lay four eggs will be strongly discouraged by natural selection, and this is sufficient to explain the extreme rarity of clutches of four.

Since, on the average, each brood of three gave rise to more young than each brood of two, a second and more complex question is why any swifts should lay clutches of two. Wynne-Edwards omitted to discuss the three reasons which I advanced earlier[3,4] and which I still hold. First, in cold, wet summers such as 1948, 1954 and 1956, swifts found it difficult to bring enough food to raise even two young successfully. Hence, in some years, birds with clutches of two have probably been at a selective advantage over those with clutches of three, and therefore a hereditary tendency to lay two eggs may persist in the population. Secondly, clutches of two are unusual at the start of the breeding season, but become commoner later, and nearly all late clutches consist of two. This regular seasonal decline could have been evolved through natural selection if, on the average, a late brood of two gives rise to more young than a late brood of three. The latter point has not been tested by experiment, and as no late swifts lay three eggs, observations alone are inadequate. However, in late summer as compared with mid-summer, the hours of daylight available for feeding are shorter, and the weather tends to be wetter, when air-borne insects are sparser, so it seems likely that late broods are more difficult to raise.

Thirdly, if cold weather occurs during the main laying period in May, those pairs which have not yet started are restrained, while it has been shown that those which have just started tend to lay their successive eggs three instead of two days apart, and often lay only two in all instead of three. This variation, unlike the others, is obviously not connected with the future raising of the brood. Instead, it is surely a consequence of the physiological strain of egg-production on the female when food is sparse, under which conditions it will presumably be advantageous to lay two eggs rather than three, even though this eventuates in a rather smaller brood.

Summing up, the normal clutch of the swift at Oxford can be satisfactorily explained through the operation of natural selection on hereditary variations, combined with two or three phenotypic variations, most of these variations being adaptations to the capacity of the parents to find food for their brood, and one to the physiological condition of the female at the time of laying. Several points in this explanation have not been proved, but all seem probable. Wynne-Edwards wrote that "on my alternative hypothesis that inter-group selection has fixed the fecundity range around the optimum level for recruitment to the population as a whole, the facts . . . seem reasonably intelligible". But he has provided no positive evidence for this statement, and in particular he has given no supporting figures for correlated variations in fecundity recruitment or size of population. Hence there is no means of knowing whether recruitment is at the optimum level'.

Turning more briefly to the red grouse *Lagopus lagopus scoticus*, this bird does not bring food to its young in the nest, so it would be extremely unlikely that natural selection would restrict brood-size for the same reason as in the swift. Instead, I would suggest that a factor of minor influence in the swift may be much more important in the grouse, namely, the physiological condition of the female at the time of laying. Jenkins *et al.*[5] showed that the heather on which red grouse basically depend for their food was in good condition in the spring in 1957, 1960 and 1961, in which years the average clutch was between 7·8 and 8·1 eggs, but that the heather was in bad condition in the spring in 1958 and 1959, when the average clutch was only 6·9 and 6·1 eggs, respectively. It is reasonable to attribute this variation to the food available to the females prior to laying. Further, this agrees with the earlier work of Siivonen[6] on other gallinaceous birds in Finland, where the partridge *Perdix perdix*, capercaillie *Tetrao urogallus* and Blackgame *Lyrurus tetrix* likewise have larger clutches in those seasons when food is more abundant prior to laying. The physiological condition of the female prior to laying may not be the sole factor determining clutch-size in gallinaceous birds; for one thing, in all species so far studied, the average clutch is smaller later in the season. But the food for the female is clearly important, and there is, once again, no evidence for Wynne-Edwards's alternative view. Indeed, he has not yet produced any positive or quantitative evidence for it in any species of birds.

[6] Siivonen, L., *Pap. Game Res.*, **17**, 1 (1956); **19**, 1 (1957); *Suomen Riista*, **12**, 43 (1958).

DR. LACK's communication clarifies some important points, among them the influence of weather at the time of laying in the swift, and the earliness or lateness of the laying date, on clutch-size. But, notwithstanding the errors in the figures I extracted on clutch-size frequencies, he does not challenge my statement that the mean clutch-size in the common swift both at Oxford and in Switzerland is well below the 'most efficient' clutch-size, this being the size that on average has yielded the largest number of surviving young. Lack outlines three suggestions as to how this situation could be accounted for on the basis of natural selection acting at the individual level.

The first concerns the cold, wet summers, when broods of two (derived from clutches of two or more) can turn out as well as or even a little better at Oxford than broods of three. In fact, such summers are in the minority, and the margin is at most rather small, so that any transient selective effect would be outweighed by the more substantial advantage to be gained in average and good years by starting off with a clutch of three. The breeding life of common swifts averages something like 4–5 years[4]; those that consistently lay three will, therefore, always tend to leave more offspring than those that lay two. In the alpine swift (*Apus melba*), studied at Solothurn, Switzerland[3], a good many parallels were found to the common swift in breeding biology, including a distribution of clutch-sizes between 1 and 4 eggs; but the extensive data in this case do not reveal any parallel switch of advantage between good and bad years.

The second, that there is a selective advantage in reducing clutch-size as the season advances, is speculative with regard to the swifts at Oxford, not being supported by adequate evidence. In the alpine swift again, where there is a corresponding fall in the frequency of 3-egg layings as the season advances, the threes nevertheless appear to remain more productive than the twos, even after the latter have come to outnumber them[7].

The third suggestion concerns the relationship established in the swifts at Oxford between the weather just prior to laying and the number of eggs laid. As Dr. Lack says, this appears to be a short-term physiological effect or phenotypic variation, modifying the innate fecundity-level. Natural selection could promote this kind of adaptability if it were hereditary and advantageous, but would be unlikely in so doing to have any effect on the basic fecundity level. Even in years when cold weather before laying depresses the average clutch-size, the threes that are laid can still be expected to do better than the twos.

I have emphasized elsewhere the fact that fertility in animals is widely influenced by contemporary events, particularly by changes in population density and economic conditions. In view of this, experiments of the kind reported by Perrins[2] seem to me to assume far too simple a conception of what is involved in determining breeding success. Environmental stress can condition such responses as the number of eggs laid, the tenacity of the parents in incubation and food-getting, the eviction or desertion of eggs or young, and so on; and where a pair of birds have become physiologically conditioned to making a reproductive effort of a certain magnitude it is hardly to be expected that they will automatically adjust themselves to a larger one, if the experimenter presents them with an extra chick. If they then fall down on the job, what valid conclusion can be drawn ?

Finality on the difficult problems discussed here is not likely to be attained by a further exchange of correspondence in *Nature*, however stimulating. It can reasonably be concluded that there are unresolved difficulties about establishing Dr. Perrins's objections[2] to the concept of intergroup selection[9], which is where the correspondence started. Whether the concept itself has suffered at all in the discussion it is for others to judge.

A Hermit Crab New to Britain

IT is of interest to record the occurrence on the shores of the Isles of Scilly of a hermit crab new to Britain. During the course of a collecting trip with my students to Porth Hellick, on the south-east corner of St. Mary's, in September of 1962 my attention was attracted by a small hermit crab with brilliant violet antennæ. Being unable to determine it to my satisfaction, I sent it to Dr. I. Gordon at the British Museum (Natural History), who identified it as a male *Catapaguroides timidus* (Roux), a species which she knew well in the Mediterranean. I have now taken a second male of the species, confirmed by Dr. R. W. Ingle, of the British Museum, this time from a bay near Gulf Rock at the south-west tip of the island of Bryher (Isles of Scilly). The two records, from widely separated localities among the islands and at an interval of two years, coupled with the fact that no systematic search has been undertaken in the interim, suggest that the species is established there.

The hitherto known localities are summarized by Bouvier[1] as the Atlantic at Roscoff and the Canaries, perhaps as far as Angola, and the eastern Mediterranean as far as the Adriatic, between shallow littoral and 1,200 m. These two records, both from littoral waters between L.W.N. and L.W.S., extend the known range of this southern species by about 1° northwards.

MICROBIOLOGY

Identification of the Bacteriostatic Component of 'Scotch' Brand of Cellulose Adhesive Tape

WE have recently shown that the 'Scotch' brand of cellulose adhesive tape of the Minnesota Mining and Manufacturing (Australia) Pty., Ltd., contains a volatile component the antibacterial activity of which is virtually restricted to coagulase-positive strains of *Staphylococcus aureus*[1]. In view of this unusual specificity it seemed important to identify the active agent.

The anti-staphylococcal component was extracted from the tape by a number of organic solvents, but not by water. For chromatography, approximately 30 g of tape was extracted with 100 ml. of boiling alcohol and the extract concentrated to a final volume of about 10 ml. About 0·2 ml. of extract was applied to strips of Whatman 3 *MM* paper 4 cm wide and developed with a variety of solvents. After drying, the position of the active component was detected by cutting the strips into short lengths which were then placed in the lids of nutrient agar plates inoculated with *Staphylococcus aureus* *E*169[1]; the absence of growth on an incubated plate indicated the presence of the active component in that section of the paper strip. With all solvents used, the active component either remained at the origin or moved with the solvent front.

Because of the apparent insolubility of the active component in water and its behaviour on conventional paper chromatograms, separation was attempted by reversed phase chromatography, using Whatman 3 *MM* paper impregnated with paraffin oil, and methanol/acetone/paraffin oil (3 : 1 : 1) as the mobile phase[2]. Under these conditions the active component was confined within R_F values of 0·4 and 0·5. Examination of strips under ultra-violet light revealed a fluorescent area extending for some distance before and behind the area within which the active component was confined. In order to remove this interfering fluorescent material, descending chromatograms were developed overnight with acetic acid/butanol/water (the aqueous phase of a 1 : 4 : 5 mixture) in which the active component was immobile. After drying, the strips were impregnated with paraffin oil and then developed with the methanol–acetone–paraffin oil solvent. Under ultra-violet light these strips showed only a slight fluorescence along the length of the paper, with an absorbing spot containing all the anti-staphylococcal activity having an R_F value of 0·46. The active spot gave no reaction with a number of detecting reagents. However, reducing activity was shown with both alkaline silver nitrate and a mixture of ferric chloride and potassium ferricyanide; these reagents showed brown and blue colorations, respectively, both streaking towards the front. In addition, strong oxidizing activity was shown with alcoholic leuco-methylene blue. These results suggested that the active component could exist in both a reduced and an oxidized state, forming a readily reversible oxidation-reduction system.

Examination of patents[3] covering the manufacture of 'Scotch' brand cellulose adhesive tape revealed that the adhesive layer of the tape contains, as an antioxidant, either 2,2′-methylene-*bis* (4-methyl-6-*tert*-butylphenol) or 2,5-di-*tert*-amylhydroquinone. When tested for anti-staphylococcal activity by direct addition to the lids of inoculated plates, only the latter substance was active.

Reversed phase chromatography of 2,5-di-*tert*-amylhydroquinone and 2,5-di-*tert*-amyl-*p*-benzoquinone (prepared by oxidation of the hydroquinone with silver oxide) gave major spots with R_F values of 0·9 and 0·5 respectively; both substances showed minor spots of the corresponding oxidized and reduced forms. These results suggested that the anti-staphylococcal activity of the tape was due to 2,5-di-*tert*-amyl-*p*-benzoquinone. This was confirmed by tests in which variants of *Staphylococcus aureus* *E*169 selected for resistance to either the tape or to 2,5-di-*tert*-amyl-*p*-benzoquinone were found to be completely cross-resistant.

The lowest inhibitory concentration of 2,5-di-*tert*-amyl-*p*-benzoquinone for *Staphylococcus aureus* *E*169 was discovered by preparing serial dilutions of the inhibitor in nutrient agar; as little as 3 μg/ml. was sufficient to reduce the colony count to less than 0·01 per cent of that on control plates. In comparison, under similar conditions a concentration of 300 μg/ml. of *p*-benzoquinone was required to produce the same reduction in colony count.

Oxford and Raistrick[4] investigated the activity of several *p*-benzoquinones against a limited range of bacterial species; they found that strains of *Staphylococcus aureus*, *Bacillus anthracis*, and *Vibrio cholerae* were particularly susceptible. In view of the role of naturally-occurring quinones in biological electron transport[5] and the inhibitory effect of *p*-benzoquinones on this system[6], it would be of interest to determine more precisely the 'spectrum' of activity of *p*-benzoquinones in relation to the distribution of ubiquinone and menaquinone in bacteria.

This work was supported in part by a grant from the National Health and Medical Research Council of Australia.

We thank Eastman Chemical Products, Inc., Kingsport, Tennessee, and the American Cyanamid Co., Bound Brook, New Jersey, for generous gifts of 2,5-di-*tert*-amylhydroquinone and 2,2′-methylene-*bis* (4-methyl-6-*tert*-butylphenol) respectively.

CYTOLOGY

Chromosome Duplication and the Cell Cycle in Lens Epithelium

PREVIOUS experiments have shown that a penetrating needle injury to the central area of rabbit lens epithelium *in vivo* produces a response in which a large number of cells synthesize DNA and divide[1]. This response begins characteristically at the site of injury and progresses farther and farther away from the wound with time. Experiments have indicated that DNA synthesis is initiated in the cells closest to the wound at about 12–14 h after injury[2]. Mitosis is first seen at about 24 h after injury. The rate at which the wave of DNA synthesis travels was calculated to be about 17 μ/h. The typical picture obtained at 48 h after injury shows a band of cells which are synthesizing DNA and completely encircle the wound. Another band of mitotic figures is seen encircling the wound and lying between the DNA synthesis band and the injury but close to the DNA synthesis band. Frequently, when the injuries are larger (these can be obtained by using a larger needle) a 'second wave' of DNA synthesis and mitosis can be seen.

The classical experiments of Taylor *et al.*[3], which demonrated in plant material that the chromosomes duplicated ι a semi-conservative fashion, indicated that examination f chromosomes with labelled precursors of DNA synthesis an be of great value.

The present experiments have yielded information egarding the mode of chromosome duplication *in vivo*, nd the nature of the cell cycle of the centrally located ells after injury.

Young American Dutch rabbits (1·5–2 lb.) were anæshetized with sodium pentobarbital and the eyes injured vith a fine steel insect needle (0 gauge) by inserting the eedle through the cornea and into the lens at right angles o the corneal surface. Tritium-labelled thymidine (spec. ct. 3 c./mM), 5 μc./ml. in Eagle's basal medium, without erum or glutamine, was injected into the anterior chamber f the eye about 18 h after injury. Colchicine (1 μg/ml. in asal medium) was injected into the anterior chamber at pproximately 46 h after injury and the eyes enucleated at 8 h. Chromosome spreads from lens epithelium were repared for autoradiography according to the technique f Srinivasan and Harding[4].

Non-radioactive preparations in which well-spread chromosomes were observed showed that the rabbit lens epithelial complement consists of 44 chromosomes. Examination of many spreads did not reveal the presence of heteroploidy. When tritium-labelled thymidine was injected at 18 h after injury and the cells fixed at 28 h, radioactive chromosomes were observed[4]. A very high percentage of chromosome spreads were labelled and the label was present along the lengths of both chromatids of the chromosome.

When tritiated thymidine was injected 18 h after injury and the eye fixed at 48 h, radioactive chromosomes were seen. Examination of the location of the label on some of the larger chromosomes revealed that the label was primarily localized on only one of the two chromatids of the chromosome. Taylor *et al.*[3] exposed plant cells to tritiated thymidine and found that the chromosomes of the first division were labelled on both chromatids. If the cell was allowed to divide once more in the absence of tritiated thymidine, the chromosomes of the second division showed label primarily on only one of the two chromatids.

Within the same preparation chromosome spreads varied in the intensity of label seen on them. This would be expected since the tritiated thymidine would have been incorporated by cells in different stages of DNA synthesis before the first division. There also seems to be asynchrony of DNA synthesis among the chromosomes *in vivo* since some of the chromosomes are not labelled at all.

The fact that radioactive chromosomes have been demonstrated after a 30-h time-interval between the introduction of the labelled precursor and fixation may not necessarily be an indication that these cells are dividing for a second time. Indeed, in other systems $S + G2$ times of a much longer duration have been reported[5]. However, the segregation of label, 48 h after injury, on the chromosomes of some cells is similar to that obtained by Taylor *et al.*[3] at the second division in cells of *Vicia faba* and also in human cells in culture[6]. This could be taken as strong evidence in favour of some lens epithelial cells dividing twice after injury. Earlier experiments by Harding *et al.*[2] showed that the cells around the injury were the first to incorporate labelled thymidine about 12–14 h after injury. The first mitotic figures appeared about 24 h after injury. Harding and Srinivasan[7], using tritiated thymidine, found that the time between the onset of DNA synthesis and cell division was about 10–12 h. Preliminary experiments indicate that the $G2$ period of these cells is 4 h or less. Therefore, the maximum time for DNA synthesis in these cells is about 8 h. When tritiated thymidine is injected into the anterior chamber at 18 h after injury, it would remain in the anterior chamber for about 2 h, since Maenza and Harding[8] showed that the concentration of tritium in the aqueous humour after 2 h is negligible. Therefore, the tritiated thymidine would remain available to the cells until about 20 h after injury. During this period of time, cells which are in all stages of DNA synthesis would incorporate the labelled nucleoside. The range of time during which one would expect to see radioactive mitotic figures of the first division is between 24 and 32 h after injury. Assuming that the $S + G2$ time remains the same for the second division as well, the generation time for the cells which divide for a second time would lie within the range of 16–24 h.

These figures are in general agreement with the timings reported by Thomson *et al.*[9], who examined the cell cycle of germinative zone cells in lens epithelium from Dutch rabbits. They found that $G2$ was between 1 and 4 h. $S + G2$ was between 9 and 13 h. These results indicate that the germinative zone cells and the cells of the central area of rabbit lens epithelium after injury have approximately the same $S + G2$ time. Similar findings have been reported for lens epithelium from very young rats[10].

This work shows that there can be a redivision of cells near the site of injury. Such a redivision occurs within 16–24 h after the first division and therefore corresponds to the timing of the second wave of stimulation of DNA synthesis.

Tetrad Analysis by Autoradiography

THE phenomenon known as 'gene conversion'[1], which results in the production of tetrads in which a pair of alleles segregates in a 3 : 1 ratio, instead of the usual 2 : 2 ratio, has been explained on the basis of a copy-choice theory[2]. Such an explanation is unacceptable unless the conservative replication of chromatids, at least in part, is also hypothesized[3]. It is generally accepted that both the DNA double helix[4] and chromatids replicate semiconservatively[5]. However, there exists evidence which suggests that the DNA double helix may replicate conservatively[6].

Evidence for the mode of chromatid replication has been derived from mitotically dividing chromosomes[6] only: it is possible that chromatids may divide conservatively at meiosis[3], but evidence on this point is lacking. We wish now to report the development of a simple system capable of providing information on chromatid replication at meiosis.

Use is made of the flowering plant *Haplopappus gracilis* ($2n = 4$). Tritiated thymidine is fed to the buds of the intact plant at the time sporogenous tissue is in the premeiotic interphase. The method of feeding the radioactive isotope is based on the use of a cotton wick as described elsewhere[7]. Following this treatment slides are made of cells in the tetrad stage; the incorporation and distribution of the label are followed by examining autoradiographs of these preparations. The low chromosome number of the plant makes it possible to predict that semi-conservative chromatid replication at meiosis will always result in equally labelled nuclei within a tetrad; whereas the presence of tetrads with unequally labelled nuclei would suggest conservative replication of chromatids.

Figs. 1–6 are photographs of autoradiographs of some of the tetrads studied. These results indicate: (1) That it is possible to label tetrads by this method. The success of the method may partly be due to the short length of time the cells take to go from premeiotic prophase to the tetrad stage in *Haplopappus gracilis*. (2) That chromosome replication at meiosis may be conservative. Figs. 2, 3, 4, 5 suggest unequal labelling of the four nuclei within a tetrad; Fig. 6 is the tetrad shown in Fig. 5, with the nuclei in focus, showing no other labelling than that in Fig. 5. Fig. 4 is of particular interest as it clearly shows that the two nuclei nearest the emulsion have little or no labelling, whereas the two nuclei farthest away from the emulsion (out of focus) are heavily labelled. Thus Fig. 4 suggests against the possibility of differential labelling of nuclei reflecting the distance of nuclei from the emulsion. Fig. 1 shows a tetrad with equally labelled nuclei.

We believe that with further refinements of our technique we should be able to reach a conclusion as to whether chromatid replication at meiosis is conservative or semi-conservative.

GENETICS

Balanced Combinations of Polygenes

Thoday and Gibson[1] have criticized some points in my discussion[2] of their results[3] in relation to Mather's ideas[4–6] concerning the action of stabilizing selection on the generation of "balanced combinations" of polygenes.

First I will follow up their points:

(1) Of course, it is possible to find some places where Mather mentions the possibility of pleiotropy of polygenes. But this is always followed by rejection of the importance of pleiotropy in quantitative genetics (for example, "Pleiotropy in the classical sense is therefore almost useless as a concept for application in biometrical genetics"[7]). Especially there was no room for pleiotropy in Mather's theory of the origin of balanced combinations of bristle polygenes which was a main aspect of my communication.

(2) The question whether Thoday's methods for the localization of polygenes are biometrical or classical genetics is only an amusing side-track leading into the terminology of polygenes. The interested reader is referred to a paper where Thoday himself[8] contrasts his "more or less classical" genetical analysis with the biometrical approach represented by quotations from Sheppard and Kempthorne, who emphasize the impossibility of recognizing individual polygenes. Thoday does not quote Mather here, from whom the following statement could have been used: ". . . the methods of analysis, so successful in the Mendelian genetics of discontinuous variation, cannot be applied where variation is continuous, because . . . the single factor cannot be separated from its fellows and followed as an individual . . ."[9].

(3) I do not think that Gibson and Thoday[3] have proved pleiotropy of the genes affecting bristle number with regard to their viability interactions. Proving pleiotropy is clearly difficult in organisms with a limited number of offspring when the developmental effects of the genes concerned are not known. But in view of the large number of generations in Gibson and Thoday's experiments and the large number of flies handled, apart from pleiotropy only very tight linkage could be responsible for the continued association of bristle and viability effects. Pleiotropy, then, seems the simplest explanation, only to be abandoned when further evidence makes it necessary.

It seems relevant to mention that Gibson *et al.*[10] claim that at least part of the effect on bristle number of the very same chromosomes under discussion here works via body size.

Reasons for thinking that pleiotropy will be the rule rather than the exception in polygenic inheritance can be found in Mayr's recent book[11].

(4) When discussing my statement that differences in bristle number are neutral or almost so in relation to natural selection Thoday and Gibson clearly missed my eference to Waddington's book[12], where the experiments and conclusions of Clayton *et al.*[13] are discussed. In addiion they can be referred to Falconer[14], where a lucid ummary of the arguments concerning the minor direct elective value of chaeta number can be found. There the results of the "extensive experiments" (there are several replicates, a feature not found in other selection experiments on chaeta number) of Clayton *et al.* are one of the main arguments.

Now we come to the main point of my communication, which was the interpretation of Gibson and Thoday's results in relation to Mather's theory of the role of stabilizing selection in the origin of balanced combinations of polygenes.

Thoday and Gibson avoid going into this. They do not dispute my statement that Mather's theory involves stabilizing selection on chaeta number itself. According to this theory natural selection would favour animals with intermediate bristle numbers because deviation from the optimal mean value is disadvantageous. This would cause an association of plus and minus factors in balanced combinations.

In Gibson and Thoday's experiments the association of plus and minus genes is not caused by natural selection on bristle number itself but by lethality, not related to bristle number, of certain combinations of their 'factors'. This seems to me an essential difference.

Therefore the statement that their experiments "demonstrate and locate in a wild stock just such a repulsion linkage balance as Mather[5] has argued should occur. . . ." is not justified.

[14] Falconer, D. S., *Introduction to Quantitative Genetics* (Oliver and Boyd, 1960).

In the comment by Thoday and Gibson[1] on a communication by Scharloo[2], they quote a paper[3], of which I was an author, in a way which seriously misrepresents its conclusions on a point which is of importance in the theory of evolution.

Scharloo had said "extensive experiments have shown that differences in this character (chaeta number) do not have much selective value". In their reply, Thoday and Gibson say the "extensive experiments" are those of Clayton, Morris and Robertson, who only say that "it has been suggested that there is little direct connection between bristle number and fitness", quoting an earlier theoretical discussion. "They do not seem to have thought their evidence firm enough to justify a statement as strong as that required to support Scharloo's thesis".

They have chosen for quotation a sentence from a section on the theoretical aspects of the dominance relationships of the genes affecting bristle characters in *Drosophila*. Contrary to their final sentence, there are in our paper strong statements about our experiments which would justify Scharloo. On presentation of the results of relaxing artificial selection, we say, "It seems from these results that many of the genes controlling bristle numbers must have little or no connection with fitness". Again in the discussion, on the same page as the sentence quoted by Thoday and Gibson, we deal with the selective forces maintaining this genetic variation in our population in the following terms: "The results of relaxation of selection in lines selected for five generations, which showed that the line means had returned only about one-third of the way back to the original mean after nineteen generations of relaxation, suggest that these forces are not very strong and that many of the genes controlling the character must be effectively neutral in their effects on reproductive fitness. We have sufficient evidence on the effects of relaxation to feel justified in relying on the results".

Our last sentence would seem strong enough to support Scharloo's thesis on this important point.

Alan Robertson

Institute of Animal Genetics,
West Mains Road, Edinburgh, 9.

[1] Thoday, J. M., and Gibson, J. B., *Nature*, **201**, 736 (1964).
[2] Scharloo, W., *Nature*, **200**, 293 (1963).
[3] Clayton, G. A., Morris, J. A., and Robertson, A., *J. Genet.*, **55**, 131 (1957).

Our criticism of Scharloo's publication has done its work in eliciting replies and demonstrating that whether, and if so when and where, polygenic balance arises through selection operating on effects of genes on bristle number, or on pleiotropic effects of those genes, through linkage of those genes to others with more drastic effects on fitness or through random effects, is a more open problem than Scharloo suggests. Prof. Mather points out to us that it has also shown the dangers of taking statements out of their context, for his comment, quoted by Scharloo, that "Pleiotropy in the classical sense is therefore almost useless as a concept for application in biometrical genetics" followed a discussion of the difficulty, general with a biometrical methodology as distinct from classical, of analysing into their ultimate units groups of linked genes (or effective factors as Mather called them) which might indeed be expected to show apparently pleiotropic action (just as they can show apparent over-dominance) even where the ultimate genes themselves did not. The effective factor is the finest unit whose properties biometrical genetics will normally reveal; but its pleiotropy cannot be held to imply pleiotropy of the genes which compose it, and indeed in cases which Mather has analysed demonstrably does not do so.

We only wish to add two points. First, we had not believed Dr. Robertson attached so firm a conclusion to the results he refers to, because the conclusion can only follow on the assumption of a large number of genes none of large effect. That some of the relevant polygenes (or effective factors) are of relatively large effect is one thing we do claim to have demonstrated. Such genes might readily be fixed in some lines in short periods of selection and these lines could not return to the starting point under relaxed selection. Second, the two "genes" we described[1], and which Scharloo chose to discuss, clearly have extraordinary properties. Base Ratios in DNA in Male and Female *Pseudococcus citri*

The mealy bug, *P. citri*, affords a unique opportunity for analysis of biochemical changes underlying chromosome behaviour. In the male embryos, the entire paternal set, that is, one half the total number of chromosomes, remains condensed in the non-dividing nuclei; this facultative behaviour is similar to that of typical heterochromatic elements such as sex chromosomes[1,2]. Experiments with tritiated thymidine show that, like heterochromatic elements in other organisms[3,4], the paternal set in the males reproduces asynchronously from the maternal, or euchromatic, set[5]. As measured by dominant lethality[2] and mutant genes[6], the paternal set is genetically inert in the males, but some 'residual' influences can be demonstrated[7,8].

Except for a few tissues, the paternal set maintains its heterochromaticity throughout the life of the male; at spermatogenesis it is segregated from the maternal, or euchromatic, set, and is not included in the sperm. In certain related forms, however, the heterochromatic state reversed during spermatogenesis and the paternal romosomes are segregated, apparently at random, to sperm, to be transmitted to offspring of both sexes[9]. seems likely, therefore, that the chromosomal changes ponsible for facultative heterochromatization are ones ich block rather than alter or destroy the genetic inmation. As a beginning we have isolated DNA from le and female insects and determined the base ratios m melting temperature and buoyant density measurents.

Mealy bugs were grown on potatoes, *Solanum tuberosum* .; the large, gravid females containing both male and emale embryos provided abundant material for establishment of experimental procedures; the second instar, prior to the extreme sexual dimorphism of later states, was used for the comparisons of males and females. No attempt was made to separate a yeast-like symbiont, present to about the same extent in males and females of the second instar; the DNA isolated includes symbiont nucleic acid also. DNA was isolated from 1 g of mealy bugs by the method of Marmur[10]. Phosphate was determined by the method of Fiske and SubbaRow[11], scaled down for the analysis of 10 µg of DNA. The best preparation of DNA had an $E(P)$ of 7,240. Chromatographic analysis was done on 1 mg of DNA from gravid females, hydrolysed 2 h in 70 per cent formic acid at 175° C. No methylcytosine was detected by Wyatt's procedure[12]. The average results from six analyses for base content are given in Table 1.

Table 1. Base Content of DNA from Gravid, Female Mealy Bugs

Base	Mole (%)
Adenine	34·2 ± 0·7
Thymine	31·9 ± 1·2
Guanine	16·2 ± 0·7
Cytosine	17·8 ± 1·3
Mole (%) guanine-cytosine	34·0 ± 1·1

Table 2. Melting Temperatures of DNA from Mealy Bugs

Source	Tm	Mole (%) guanine-cytosine
Gravid females	84·4 ± 0·35	37·5 ± 1·0
Second in	84·9 ± 0·20	38·7 ± 0·6
[illegible]	4·9 ± 0·28	38·7 ± 0·8

[illegible] were determined on a *DU* [illegible] a heated cell compart- [illegible] M sodium chloride– [illegible] ng temperatures of [illegible] female second [illegible] mole per [illegible] ublished

[illegible] males is [illegible] males is [illegible] f 1·39. [illegible] omatin

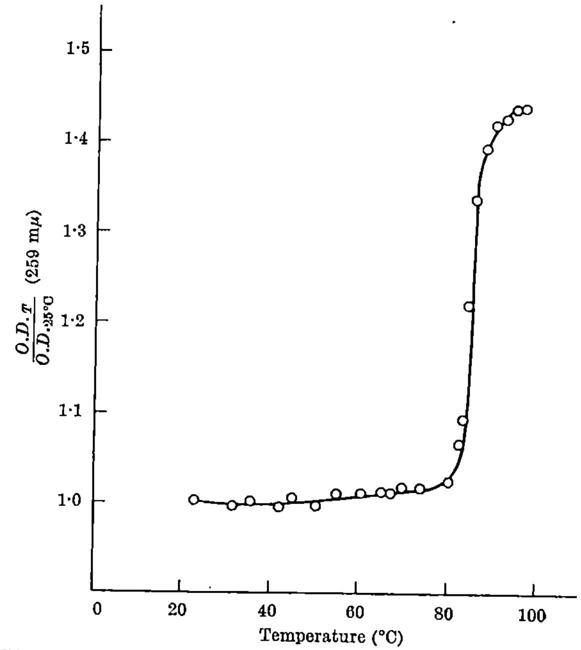

Fig. 1. Melting temperature profile of DNA from male mealy bug. Solvent used was 0·15 M sodium chloride–0·015 M sodium citrate. (Optical densities uncorrected for volume expansion)

The buoyant densities of DNA from both male and female second instar insects was 1·695 ± 0·001, corresponding to 35·8 ± 1·0 mole (per cent) guanine-cytosine[14].

The difference in base ratios by these three methods is not outside the variation reported in the literature[14]. It may be concluded that there is no evidence of a difference in base ratios greater than 1 per cent between DNA from male and female mealy bugs. Although genetic information no doubt could be destroyed without producing grossly detectable changes in base ratios, the fact that such cannot be demonstrated here is certainly in conformity with, rather than opposed to, the independent conclusion, from reversals of facultative heterochromatization, that the genetic information is masked rather than disrupted. Work is in progress to determine what differences may be found in other chromosomal components.

Buoyant densities in $Cs^{14}Cl$ were determined by Dr. John Hearst, of the Department of Chemistry, University of California, at Berkeley. The λ phage DNA used as a density standard was a gift of Dr. Monica Reilly, of the Department of Microbiology, University of California, at Davis.

This investigation was supported in part by a research grant (*GB*413–Brown) from the U.S. National Science Foundation and (*G*–4236–McLaren) from the National Institutes of Health, U.S. Public Health Service.

FORTHCOMING EVENTS

Monday, July 6

Royal Society of Medicine (at 1 Wimpole Street, London, W.1), at [illegible] p.m.—Prof. E. B. Chain, F.R.S.: "Some Contributions from Chemical Microbiology to Medicine" (Jephcott Lecture).

Tuesday, July 7

Royal Society of Medicine (at 1 Wimpole Street, London, W.1), at 5.30 p.m.—Annual Meeting.

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Assistant Lecturer in Geography—The Assistant Secretary, London School of Economics and Political Science, Houghton Street, London, W.C.2 (July 8).

Assistant Lecturer (with a good honours degree) in Geography—The Registrar, King's College (University of London), Strand, London, W.C.2 (July 8).

Assistant Cataloguer (graduate with good academic qualifications and experience or training in librarianship, and preferably with professional diplomas or experience) in the University Medical Library—The Registrar, The University, Manchester, 13 (July 10).

Lecturer in the Department of Medicine at the Royal Infirmary, Edinburgh—The Secretary, The University, Edinburgh (July 10).

Lecturer or Assistant Lecturer (with a special interest in inorganic *chemistry and preferably some teaching and research experience*) in the Department of Chemistry—The Secretary (F), Chelsea College of Science and Technology, Manresa Road, London, S.W.3 (July 10).

Soil Chemist (with an honours degree or equivalent qualification), for duties which will include advisory work in soils and the supervision of routine soil analysis—The Secretary, School of Agriculture, West Mains Road, Edinburgh, 9 (July 11).

Assistant Lecturer (*with a degree in mathematics or the physical* sciences and preferably some postgraduate experience) in Computing—The Registrar, University College of North Wales, Bangor, North Wales (July 13).

Demonstrator (with an honours degree in chemistry or biochemistry and prepared to engage in research in biochemistry with a view to obtaining a higher degree in this subject) in the Department of Biochemistry—The Dean, St. Thomas's Hospital Medical School, London, S.E.1 (July 13).

Sub-Dean (preferably with experience as a university lecturer in science and also some administrative experience) in the Faculty of Science—The Registrar, The University, Liverpool, 3 (July 13).

Research Assistant (with a degree in pharmacology, physiology or a related subject), to join a team concerned with the identification of a urinary polypeptide which inhibits gastric secretion—Prof. H. O. Schild, Department of Pharmacology, University College, Gower Street, London, W.C.1 (July 15).

Graduate Research Assistant (with a degree in science or engineering, and competent to set up experimental apparatus and equipment involving vacuum production and measurement, power supplies up to 100 kV, electrical circuits and *controls, oscillographs and electronic measuring devices,* and preferably some knowledge of optics or spectroscopy) in the Research School of Physical Sciences, to take part in the general field of the physics of ionized gases—The Registrar, Institute of Advanced Studies, Australian National University, Box 4, G.P.O., Canberra, Australia (July 17).

Assistant Lecturer in Geology at Queen's College—The Secretary, University of St. Andrews, Queen's College, Dundee, Scotland (July 18).

Special Research Assistant to Dr. J. W. Smith in the Department of Chemistry, for work on the nature of complexes formed between acids and amines in aprotic solvents—The Secretary, Bedford College (University of London), Regent's Park, London, N.W.1 (July 18).

Assistant Veterinary Investigation Officers (men or women aged 23 or over, M.R.C.V.S., and preferably with postgraduate research experience) for at least 10 posts (mostly in provincial towns in the southern part of England)—Civil Service Commission, Savile Row, London, W.1, quoting Ref. 266/64 (July 20).

Demonstrator (with, or taking, an honours degree in botany, and either *have studied or have an interest in bacteriology or microbiology*) in the Department of Botany—The Registrar, The University, Nottingham (July 20).

Lecturer or Assistant Lecturer (medically qualified or non-medically qualified) in the Department of Bacteriology—The Registrar, The University, Leeds, 2 (July 20).

Demonstrator/Senior Demonstrator (with experience in the fields of *geophysics, solid state physics, or optical spectroscopy*) in the Department of Physics—The Registrar, The University, Newcastle upon Tyne, 2 (July 22).

Assistant Lecturer or Lecturer (veterinary graduate) in Veterinary Anatomy—The Registrar, The University, Liverpool, quoting Ref. No. CV/204/N (July 24).

W. R. Grace Chair of Chemistry at the University of the West Indies, St. Augustine, Trinidad—The Secretary, Inter-University Council for Higher Education Overseas, 33 Bedford Place, London, W.C.1 (July 28).

Lecturer or Assistant Lecturer in the Department of Inorganic and Structural Chemistry—The Registrar, The University, Leeds, 2 (July 30).

Lecturer (preferably with research experience on polymerization reactions) in the Chemistry of High Polymers in the Department of Textile Industries—The Registrar, The University, Leeds, 2 (July 30).

Post-doctoral Fellow for research into the chemistry of hydrocarbon metal nitrosyl complexes—The Professor of Chemistry, The Royal College of Science and Technology, George Street, Glasgow, C.1 (July 31).

Research Fellow (medical or non-medical graduate) in Cancer in the Cell Metabolism Unit—Dr. R. A. Holman, Department of Bacteriology, The Welsh National School of Medicine, 34 Newport Road, Cardiff (July 31).

Reader (with a Ph.D. or higher degree in microbiology and have made a substantial contribution to research in some field of microbiology) in Microbiology at the University of Queensland, Australia—The Secretary, Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (London and Brisbane, August 7).

Curator (with specialized knowledge of early scientific instruments and their history) of the Museum of the History of Science—The Registrar, University Registry, Oxford (August 31).

Lecturer (graduate in any subject with an interest in any branch of *educational studies*) in the Department of Education, University of Adelaide, Adelaide, South Australia—The Secretary, Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia, August 31).

Assistant Director of Research in Mechanics of Solids in the Department of Applied Mathematics and Theoretical Physics—The Secretary of the Appointments Committee, Faculty of Mathematics, The University, Arts School, Bene't Street, Cambridge.

Assistant Lecturers and Lecturers (with a good honours degree or an honours diploma in technology in electrical engineering and some industrial experience) in Electrical Engineering with opportunity to specialize in any branch—Head of the Department of Electrical and Electronic Engineering, Northampton College of Advanced Technology, St. John Street, London, E.C.1.

Botanist (Plant Pathologist) (*national of the United Kingdom or the* Republic of Ireland, with an honours degree in botany or agricultural botany and at least one year's postgraduate training in plant pathology) in Uganda *to diagnose the cause of crop diseases and to recommend control measures,* to control trials on the comparison of methods for the control of crop diseases and to study the epidemiology of specific crop diseases and to relate any findings to field practices—Appointments Officer, Room 301, Department of Technical Co-operation, Eland House, Stag Place, London, S.W.1, quoting Ref. RC 213/183/09.

Departmental Research Assistant (Physics/Engineering), to design, assemble and test *electromagnetic flowmeter heads for measuring blood* flow—Dr. D. G. Wyatt, Nuffield Institute for Medical Research, 43 Woodstock Road, Oxford.

Experimental Officer or Senior Experimental Officer (physicist or engineer with graduate or equivalent qualifications) in Electronics, to set up a group responsible for the maintenance and design of electronic equipment used for teaching and research in the Physics Laboratory—The Professor of Experimental Physics, Physics Laboratory, University of Sussex, Falmer, Sussex.

Head of the Department of Electrical Engineering—Clerk to the *Governing Body, Borough Polytechnic,* Borough Road, London, S.E.1.

Junior Hospital Medical Officer (Psychiatry)—The Physician Superintendent, Oakwood Hospital, Maidstone, Kent.

Laboratory Instructor (graduate with suitable experience) in the Department of Inorganic and Structural Chemistry, to assist in teaching modern inorganic and analytical chemistry at all levels up to Final Honours Degree standard—Prof. H. Irving, Department of Inorganic and Structural Chemistry, The University, Leeds, 2.

Lecturer (national of the United Kingdom or the Republic of Ireland, training and experience in agronomy (arable crops), practical experience of soil conservation practices in arid, tropical or semi-tropical areas, and preferably experience of practical demonstration and lecturing in these subjects) at Karaj Centre, Iran, to train students on soil conservation practices in arid, tropical and semi-tropical areas—The Appointments Officer, Room 301, Department of Technical Co-operation, Eland House, Stag Place, London, S.W.1, quoting Ref. RC 213/86/01.

Mathematician—The Director of Science Studies, Brock University, St. *Catharines, Ontario, Canada.*

Mathematician (well qualified) to teach mathematics to all levels—The High Master, The Manchester Grammar School, Manchester, 13.

Physicist or Physical Chemist (degree standard, preferably with some research experience in rheology) to be concerned with *a fundamental* research programme in polymer melt rheology, for which a Weissenberg Rheogoniometer is available—The Secretary, Rubber and Plastic Research Association of Great Britain, Shawbury, Shrewsbury, Shropshire.

Post-Doctoral Fellow (pure or applied scientist with, or about to obtain, the degree of Ph.D.) in the Department of Chemical Engineering, to investigate dimensional changes occurring in polyurethane foams consequent upon the sorption of water vapour—*The Registrar, University College* of Swansea, Singleton Park, Swansea.

Post-Doctoral Fellow (spectroscopist, physicist or physical chemist) in the Department of Chemistry, to co-operate with Dr. A. J. Hyde on the determination of molecular space-time correlation functions in liquids using scattering from laser beams—Dr. Hyde, Department of Chemistry, The Royal College of Science and Technology, Glasgow, C.1.

Research Assistant or Research Technician (A.I.M.L.T. or equivalent or degree, and preferably experience of tissue culture, bacteriological or serological techniques), to take part in an investigation of the synthesis of antigens by cells growing *in tissue culture* system, and immunological and biochemical studies on cellular antigens—Department of Pathology, The University, Cambridge.

Research Assistant (physicist or electrical engineer with a good honours degree and preferably some research experience) in the Department of Building Science, to take part in a study of the thermal response of buildings to climatic variations and its electrical simulation—The Registrar, The University of Liverpool, Liverpool 3, quoting Ref. No. CV/211.

Research Assistants and Students for research in the following fields: properties of gaseous ions; physico-chemical aspects of cumbustion; inter*molecular forces in solutions*; inorganic complexes; structure and reactivity of organosilicon compounds; selected topics in natural product chemistry; and the kinetics of polymerization processes—Head of the Department of Chemistry, College of Advanced Technology, Gosta Green, Birmingham, 4.

Research Assistants (eligible to register as *full-time* students for a higher degree of the University of London) in the Department of Botany and Zoology, one in Botany (cytochemistry or chromosome studies), two in *Zoology (freshwater ecology and histology of marine mammals)*—Head of the Department of Biology, Sir John Cass College, Jewry Street, London, E.C.3.

Research Fellow or Senior Research Fellow (social scientist with research experience) to take a leading part in a *project concerned with some* of the sociological aspects of the construction of a new university—The Secretary and Registrar, Bristol College of Science and Technology, Ashley Down, Bristol, 7, quoting Ref. CST 64/69.

Research Students in Biochemistry—The Registrar, The University, Hull.

Research Students in Physics of the Solid State—Prof. G. W. Hutchinson, The University, Southampton.

Scientific Information Officers (Abstractors) (with a degree in agriculture or natural sciences, together with (a) ability to abstract from Russian or (b) ability to abstract from Japanese or Chinese)—*The Director,* Commonwealth Bureau of Pastures and Field Crops, Hurley, near Maidenhead, Berks.

Soil Chemist (with either an honours degree in agricultural chemistry (soils and plants), *or a degree in chemistry* with postgraduate experience in agricultural analysis (soils and plants), and preferably experience in soil and plant analysis) with the East African Common Services Organization, to carry out and supervise soil and plant analyses and to help develop and investigate new methods—The Recruiting Officer, Room 301, Department of Technical Co-operation, Eland House, Stag Place, London, S.W.1, quoting Ref. RC 213/214/04.

Technician or Senior Technician (*preferably* with experience in the handling of radioactive materials) in Chemistry—The Director, Scottish Research Reactor Centre, East Kilbride, near Glasgow.

AIMS AND OBJECTIVES IN EXPANDING HIGHER EDUCATION

IN a talk "Educating Half Ourselves", broadcast on the B.B.C. Third Programme and published in *The Listener* for March 19, Dr. G. H. Bantock suggested that neither the authors of the Robbins Report nor Dr. A. E. Sloman in his Reith Lectures, "A University in the Making"*, had appreciated the extent to which the crisis in education to-day arose out of a crisis in the level and in the range of consciousness. Accordingly, both the Robbins Report and the Reith Lectures were too much concerned with organization to the exclusion of cultural needs. Little thought was given to the cultural needs of the many students to whom the way to further education was now opened and whose home-life and surroundings did not equip them to explore it fully.

Properly conceived, Dr. Bantock pointed out, a culture embraced the ways in which we structured and communicated our common world, intellectually and emotionally, and on it depended our ability to understand the world in its various guises; from it there stemmed the spiritual strength or weakness of a generation. It formed, he rightly maintained, an essential part of the human predicament in an advanced industrial society, and the dangers involved intensified as automation, for example, extended. Yet, on all these dilemmas and cultural needs, the Robbins Report and the Reith Lectures had little or nothing to say. Their conception of the service which the university should render to the community was that of community service, the supply of special skills, rather than of the development of human personality and the equipping of men and women to meet the demands of the age in which they live.

Dr. Sloman did indeed suggest that a university should stimulate the curiosity of its students with subjects relevant to the social, cultural and scientific realities of to-day and to their own personal lives, and provide both a specialized training in depth and a truly liberal education. While the University of Essex is to be restricted initially to the physical sciences, to social studies and to comparative studies, there is to be a centre for creative arts, though its nature is not made clear, and, in discussing what he called the "fulfilment of lives", Dr. Sloman was concerned with the physical conditions of residence rather than the psychological or cultural needs stressed by Dr. Bantock. No more than the Robbins Report did he desiderate an education that would meet deeper requirements of individuals living in a civilization faced with a crisis of abundance, implying not only much more leisure in the near future but increased social mobility—in an age which from the cosmic to the personal level can fairly be characterized as an age of anxiety.

In that context the failure of the Robbins Committee to consider at any length the purposes which the vast extension of higher education is to serve appears as an unmistakable weakness, and, for all his admission at the outset that a new university must decide at the start what kind of a university it is going to be, Dr. Sloman equally failed to ask the fundamental questions about education and society. Much indeed that he said was sound and unexceptionable: on the relations between research and teaching; on self-government; and on the relations between the university and the community, including industry. Nevertheless, his approach was too pragmatic and seemed to lead to a subservience to professional or industrial needs that overrides those of the individual or even the deeper needs of society itself, which the rising debate on automation and leisure is now tending to bring to the forefront.

Dr. Bantock himself did not indeed ignore the requirements of technological change which a system of education must meet and for which proposals for expansion may reasonably be expected to provide. What he argued was that even those technical needs cannot be properly met without a clear conception of the purpose of education—of university education in particular, and of what constitutes an educated man or woman. If higher education is indeed to be expanded essentially to increase productivity, then we are in grave danger of becoming enslaved by the immediate necessities of our time, and unable to find the detachment which will permit a true perspective and the service of the deeper and enduring needs of society. Conceived and pursued in that way the expansion of higher education could indeed betray society, and the universities would fail to fulfil their most important function.

Prof. P. M. S. Blackett did not fall into this error in his Granada Lecture, "The Universities and the Nation's Crisis", which he delivered in October 1963, just before the Robbins Report was published and later published in *Advancement of Science* (20, 379; 1964). Prof. Blackett saw the greatest act of communication in the modern world in the passing on, to each new generation, the knowledge, wisdoms, skills and visions of the older generation. Much of this act of communication takes place in the universities, and it was for the complete communication that Dr. Bantock pleaded. While, however, Prof. Blackett did not assume that a university education was always a good thing for all young people and actually urged expansion on a somewhat larger scale than, in the event, the Robbins Report recommended, he was more alive to the human aspect and he urged as one reason for the expansion of the universities the contribution it could make to the progress and welfare of the newly independent nations.

This would be rendered in three ways. First, by providing academic and other professional staff to work in these countries, at their request, on secondment from professional posts in Britain. Secondly, by providing still wider training facilities in Britain's universities, mainly for postgraduate and post-doctoral work. Thirdly, by increasing Britain's financial aid to those emergent countries, within the limits set by the health of the British economy as a whole and its foreign exchange position in particular.

In so far as Prof. Blackett sees university expansion as directed to the proper training and use of all the brains which Britain possesses, his approach could equally be described as pragmatic, but the distinction lies in the interpretation of 'proper' and the attention given to other elements than the acquisition of technical skills. Even at the pragmatic level the omission of the Reith Lectures or the Robbins Report to deal adequately with the purpose of university education is unfortunate. It leads to a tendency to disregard some of the changes in the character of the university student now that increasing numbers are drawn from homes with little or no tradition of learning or culture. Some of these changes were discussed by Mr. D. Johnson in a talk broadcast on the B.B.C. Home Service and later published in *The Listener* (71, 185; January 30, 1964), and if serious attention is given to the purpose of a university education, such weaknesses as immaturity, irrelevance, or decreasing independence cannot be disregarded.

---

* *A University in the Making*. By Dr. Albert E. Sloman. (The Reith Lectures 1963.) Pp. 90. (London: British Broadcasting Corporation, 1964.) 12*s*. 6*d*.

Over the past ten years, Mr. Johnson finds students becoming less independent and characterized by a great personal immaturity, surrounding an acquired and perhaps shallow intellectual maturity. As he rightly observes, education should at least affect the character and outlook of the student and promote a link between a student's approach to the past and his or her approach to the present. Something of Mr. Johnson's mind would seem to be influencing the plans which Dr. Sloman outlined for the new University of Essex, for those plans should encourage self-confidence among students, though they are not free, as already suggested, from some danger of subservience to other interests. Only, however, such an understanding and sympathetic approach to the human problems of the student such as Mr. Johnson displays in this talk, however, will suffice to meet the fundamental need, but that found comparatively slight expression when the Conference of the Universities of the United Kingdom discussed the Robbins Report in December 1963.

This is not to suggest that the Conference was unmindful of such issues or obsessed with organization. There was no complacency, and Lord Robbins himself insisted that there was too much slack in Britain's present organization—in the defective use of man-power, of obsolete teaching methods, etc.—and pleaded for a new and impartial outlook on many subjects, such as that of the teacher training college. Nevertheless, neither he nor other speakers raised the issue of the purpose of university education. While the reference by Dr. B. V. Bowden (as he was then) to the way in which the American universities and technological institutions recognized a fundamental obligation to try in every way possible to help industry was not unreasonably pragmatic, that could not be said of Mr. D. R. O. Thomas's endorsement of the paragraphs in the Robbins Report on education as an investment. These paragraphs formulate a view of education as a coldly calculated investment to promote national productivity such as to justify the hardest comments of Dr. Bantock. They completely overshadow the earlier reference in the Report to the transmission of a common culture and common standards of citizenship as among the aims of higher education—aims which Mr. Thomas described as magnificent in concept and clarity.

For all the characterization of this particular objective in the Robbins Report as 'fundamental' and the observation that universities and colleges have an important part to play in the general cultural life of the communities in which they are situated, there is unfortunately too much support for Dr. Bantock's belief that, in the expansion of higher education, there is too much conc
with organization and that insufficient thought is b
given either to its purpose or to the needs of the
dividual student. Nor is concern on these points remo

with no clear conception of the real purposes of university education is a sure way to frustration and to waste national resources and talent, rather than to achieve the return on investment urged by the Robbins Committee. Even though expansion is already beginning, we would do well to look at our real objectives and think deeply about the human needs of society, including the potential students, before committing irrevocably limited resources on a scale and in ways that are ill-judged to serve effectively the long-term needs of individuals or society, even of industry itself.

EXPERIMENTAL PSYCHOLOGY

Traité de Psychologie Expérimentale

Sous la direction de Paul Fraisse et Jean Piaget. Fascicule 1: Histoire et Méthode. Par Jean Piaget, Paul Fraisse et Maurice Reuchlin. Pp. 191. 12 francs. Fascicule 2: Sensation et Motricité. Par Henri Piéron, René Chocholle et Jacques Leplat. Pp. 161. 12 francs. Fascicule 5: Motivation, Émotion et Personnalité. Par Joseph Nuttin, Paul Fraisse et Richard Meili. Pp. iv+226. 15 francs. Fascicule 6: La Perception. Par Jean Piaget, Paul Fraisse, Éliane Vurpillot et Robert Francès. Pp. 231. 15 francs. (Paris: Presses Universitaires de France, 1963.)

TRAITÉ de Psychologie Expérimentale is the first treatise of its kind since the Harvard *Handbook of Experimental Psychology*, edited by S. S. Stevens and published in 1951. In a way, it is a little odd that it should come from France, for although there has been a distinguished French psychological tradition, experimental psychology has never held a central place in it. Nor has the output of the French psychological laboratories been large or, for that matter, particularly important. It might seem, however, that interest in experimental psychology is rapidly growing in the French-speaking countries and this treatise will undoubtedly do much to shape its development.

The complete work is to comprise nine volumes, covering the experimental psychology of sensation and perception, learning and memory, the psychophysiology of behaviour, intelligence, communication and decision processes, motivation and personality, and experimental social psychology. Inevitably, the choice of topics reflects both contemporary fashion and the special interests of the Editors. It also reflects in some degree the availability of contributors, all of whom appear to have been drawn from France, Belgium and Switzerland. Whether this geographical limitation was altogether wise is debatable: in cultural as in economic matters national pride can be a potent source of inflation.

The first volume, *Histoire et Méthode*, starts with an account of the evolution of experimental psychology by Prof. Paul Fraisse. Although perfectly adequate, it leans heavily on secondary sources (particularly Boring's *History of Experimental Psychology*) and the judgments expressed are for the most part conventional. It is followed by chapters on experimental method by the same author and on psychological measurement by Dr. M. Reuchlin. These are quite well done, if unexceptionable. More exciting, however, is Prof. Piaget's discussion of explanation in psychology and the problem of psychophysical parallelism. This is both lucid and original and it is interesting to note that the author expresses hope in the possibilities of a sophisticated isomorphism. This chapter will interest philosophers of science as well as experimental psychologists, and should be widely read.

The second volume, entitled *Sensation et Motricité*, opens with a long and detailed account of psychophysics by Prof. Henri Piéron, whose grasp has clearly been in no way impaired by age. Indeed, the author passes from classical Fechnerian psychophysics to modern decision theory with masterly ease and detachment. Dr. R. Chocholle writes on reaction times, showing himself to be well acquainted with the ways in which information theory has been applied to their measurement. Dr. J. Leplat considers human sensori-motor performance; recent British work is particularly well represented in his survey. This whole volume is altogether of much interest to British experimental psychologists and can be warmly recommended to their attention.

The fifth volume, *Motivation, Émotion et Personnalité*, is inevitably less satisfactory. As is well known, the topics with which it deals are fraught with snags, conceptual, linguistic and methodological, and have on the whole proved resistant to experimental analysis. However, Dr. J. Nuttin surveys experimental investigations of drives and incentives with commendable balance, covering both animal and human enquiries. His knowledge of recent American work is particularly impressive. Prof. Fraisse writes on emotion; if he has rather little to say, this is due largely to the paucity of convincing experimental data. Finally, Dr. R. Meili outlines investigations of personality structure, mainly the large-scale, statistical variety which Prof. Eysenck and others have made their special province. (But he does have a kind word or two for psychoanalysis.) Although little positive emerges, the author concludes that thirty years' work on personality has at all events led to a clearer conception of the problems and of the methods which might lead to their solution. Possibly.

The sixth volume is concerned with perception. As might be anticipated, Prof. Piaget leads off with an account of the genetic development of perception, much of the material being derived from the work of his own laboratory. Prof. Fraisse writes on time perception, a topic to which he has himself devoted much study. Dr. E. Vurpillot writes on space perception; this chapter is impressive and might well justify translation as a monograph. Finally, Dr. R. Francès discusses form and object perception. This is a bit limited, no consideration being given to recent investigations of form perception in animals, which have given new impetus to the whole field of enquiry. Oddly, too, auditory perception is little discussed and tactual perception scarcely at all. but perhaps these omissions will be remedied in later volumes. Nor do neurophysiological aspects of perception receive their due.

This treatise is comprehensive, scholarly and well balanced. Although drawing heavily on American (and to a lesser extent British) sources, it certainly cannot be regarded merely as an attempt to market Anglo-American psychology in a form appropriate for Continental consumption. It does distil a flavour of its own, critical, at times ironic, and above all lucid. It will have both impact and influence, and the Editors deserve congratulation on their enterprise. Psychologists everywhere will await the forthcoming five volumes with lively anticipation.

O. L. ZANGWILL

SOCIAL MISBEHAVIOUR

Crime and the Social Structure

By Dr. John Barron Mays. (Society Today and Tomorrow.) Pp. 256. (London: Faber and Faber, Ltd., 1963.) 30*s*. net.

DR. J. B. MAYS has in recent years made a significant contribution towards our understanding of some of the intractable problems of juvenile delinquency, notably in his investigation, published in 1959, appropriately called *On the Threshold of Delinquency*. It was, therefore, with keen anticipation that I looked forward to his latest book *Crime and the Social Structure*.

The central thesis of this investigation is that "society itself is in some respects criminogenic and to a considerable extent precipitates its own delinquency". There is nothing really novel in this argument, but what is unusual is the extent to which Dr. Mays tries to prove that "criminal behaviour arises naturally enough out of the ordinary daily affairs in which all of us are engaged". But, does he provide the proof to validate his thesis? In my view he does not, despite the wide range of social factors associated with crime which he has examined.

There is, of course, a real difficulty in making any attempt to put forward a particular thesis about the cause of crime, and that is the difficulty of finding, by scientific methods, supporting evidence. Dr. Mays has had to rely in the main on his own experiences as a youth club leader, and on the research he carried out among the boys of the youth club with which he was connected, and of course on the results of research carried out by others in Britain and the United States. Unfortunately, one cannot satisfactorily translate to Britain the results of research carried out in the United States, for as Dr. Mays admits "British society is in some important respects very unlike American". Furthermore, much of the research carried out in limited areas of Britain has not been repeated elsewhere and therefore he has to rely all too often on 'localized' evidence, as, for example, when he argues that the offences of the youth club members he knew in Liverpool were caused essentially by the environment in which they lived. The interesting question is, would these same boys have committed offences had they been born and brought up in any other part of Britain? Unlike the natural scientist the social scientist cannot easily repeat his experiment, and therefore that interesting question cannot readily be answered.

For anyone who is unfamiliar with theories of the causation of crime and such facts as are known about crime in Britain this book provides a useful introduction. Dr. Mays, as always, writes extremely well and, unlike many writers on criminology, he avoids jargon. This is a very readable book, it stimulates thought about criminal behaviour and draws a useful distinction between 'normal' and 'abnormal' crime which helps the reader to see in perspective the alleged increase in criminal behaviour. With his plea that "we should take a hard long look at the nature of our society to see whether or not there are social and environmental forces which foster delinquent attitudes" one must agree whole-heartedly, but has he himself shown us what these forces are? I'm afraid the answer must be no, and having finished reading this book I was left with the uneasy feeling that the claim made on the dust-jacket that Dr. Mays "reveals the relationship between long-established institutions and criminal attitudes and behaviour" is not substantiated.

D. C. MARSH

THE WAYS OF SCIENCE

The Nature of the Natural Sciences

By Dr. Leonard K. Nash. Pp. xix+406. (Boston and Toronto: Little, Brown and Company, 1963.) n.p.

Philosophy of Science

The Delaware Seminar. Vol. 1, 1961–1962. Edited by Bernard Baumrin. Pp. xvi+370. (New York and London: Interscience Publishers, a Division of John Wiley and Sons, 1963.) 75s.

THE author of *The Nature of the Natural Sciences* is a professor of chemistry at Harvard University, and as a member of Conant's Harvard General Education Programme for the teaching of science to non-scientists he has always been particularly conscious of the need to give an answer to that most difficult of all questions, "What is science?". In this book he sets out to sketch such an answer, with refreshing simplicity of approach and copious illustration from actual cases of our scientific past and present. His objective, he explains, is not to present the reader with some abstract 'ideal science' which may be found in logicians' text-books, but to attend closely to its dynamic aspects though all the time keeping attention directed towards the history, the philosophy, the internal organization of science, its social ties, and so forth. This is a formidable programme, and one will not, for that reason, expect a very searching enquiry at all levels; but, as an introductory exploration of a many-faceted field, the book has its value. Its examples are chosen so as to be comprehensible to the scientific amateur, but it should be noted that they turn out to differ not so very much from the stock-in-trade of the defamed logician: Boyle's Law, Archimedes's Principle, the Kinetic Theory of Gases, Newton's theory, Ptolemy and Copernicus spatter the pages, even though supplemented by such 'modern' representatives as Moseley's law and Mendel. Again, for someone who sets out to offer us a fresh appraisal of an old subject from a working scientist's point of view, the book is curiously cluttered up with quotations from the pens of a vast number of philosophers, chosen quite at random. This gives the enterprise a somewhat eclectic appearance, and a teacher should be warned to press the work into students' hands only on condition that he is prepared to supervise their reading himself.

This said, I must nevertheless register my approval of the author's attempt to present science neither as a straightforward enterprise of collecting facts followed by generalization and explanation, nor as a purely deductive and theoretical enterprise with only an occasional exploration into the laboratory. On the contrary, the two sides of science, intelligible explanation and theoretical approach on one hand, and the whole apparatus of instrumental control on the other, are presented with illuminating care. The element of 'colligation by laws' in the construction of scientific concepts is emphasized, as is the weight of certain 'methodological principles', such as those of parsimony, penury, clarity and analogy all acting as often unconscious devices in the day-to-day operations of the scientist, particularly when faced with the task of the choice between hypotheses.

Prof. Nash is always concerned with exposing the many-sidedness of the scientist's thinking. The almost dialectical way in which the demand for 'intelligibility' of explanation—misunderstood by the early scientists and philosophers as the request for 'self-evidence'—is checked by certain constraints, for example, eschewal of a total explanation of everything, the need for experimental control coupled with a rigidly deductive stratification. Other methodological principles discussed are those of continuity, determinism, corrigibility. There are the usual chapters on theories and models, sympathetic discussions of the claim (ultimately rejected) that there is "*a* scientific method", and considerable attention is directed towards psychological and social factors inherent in scientific research experience. For good measure, at the end we get also a discussion of questions that have exercised academic philosophers since the seventeenth century, such as the debate of 'realism' versus 'phenomenalism', the author arguing for a particularly trivialized version of optimistic realism.

Philosophy of Science is far headier stuff, with contributions by some of the most eminent of our contemporary philosophers, mathematicians, biologists and physicists to the Delaware Seminar, a running colloquium intended to be indicative of work in progress in the philosophy of science. This is the first of a series. Here, issues are argued with greater care and attention to detail, though, of course, with less relevance for the everyday concerns of the working scientist. This is, however, a price that has to be paid by every branch of intellectual endeavour as soon as it comes of age: in this case, progressive depth in its searchings and the establishment of an agreed forum of discussable 'technical' problems, however much these may originally have arisen out of the corpus of scientific activity itself, soon take on the aspect of a separate academic discipline; nor is it easy to see how an honest interest in truth could prevent such a splintering process from coming to pass. Philosophy of science, in this respect, is in the condition in which dynamics, geology, psychology, and most other scientific disciplines have found themselves at their own respective periods of gestation. The complication, however, in the present case is that philosophy of science is (and always has been) a tremendously composite hotchpotch of interests and influences; ranging from the extreme of the foundations of logic and mathematics—not to mention the metaphysical enterprises of the great classical philosophers, many of whom saw themselves primarily as writers on the foundations of science—to the investigations of the statisticians and probability theorists into the theory of games.

The Delaware volume is evidence of a similar width of interests. Its six main parts include sections on "Scientific Explanation and Prediction"; "Philosophical Aspects of the Foundations of Mathematics"; "Philosophical Aspects of Biology"; "Philosophical Aspects of the Social Sciences"; and finally "Philosophical Aspects of Physics". The section on the foundations of mathematics argues the virtues (and vices) of Platonism and Nominalism, through an explanation of the notion of 'existence', of sets, for example. Another article is concerned with the notion of mathematical truth. A. Landé, in "Causality and Dualism on Trial", reiterates his thesis, already made in an earlier book of his, seeking an interpretation of the formalism of quantum mechanics primarily in terms of a particle model with an inbuilt statistical element from the start. Probabilistic theory is then considered a fundamental and irreducible element in all physical situations.

Naturally, as always in a co-operative effort, the value, thoroughness and relevance of the individual contributions vary tremendously; but as an insight into the workshop of contemporary discussions on the logic of the sciences and mathematics this book can be strongly recommended. GERD BUCHDAHL

SCIENCE IN THE HISTORY OF CIVILIZATION

Ancient and Medieval Science from Prehistory to A.D. 1450

Edited and with a General Preface by René Taton. Translated by A. J. Pomerans. (A General History of the Sciences.) Pp. xvi + 552 + 48 plates. (London: Thames and Hudson, Ltd., 1963.) 126*s*.

THIS is the first volume of a series, published in 1957 in French, which aims to bridge the gap between specialized papers in the history of science and general history written for the educated man. The apparatus of historical scholarship and critical discussion have been kept to the minimum, and extensive bibliographies have been included to enable readers to pursue particular interests. Each major section has been written by a specialist. This volume covers the period from prehistory to A.D. 1450, and covers not only the ancient civilizations which provide the first chapters of every general history of science—Egypt, Mesopotamia and Greece—but also China, India, ancient and medieval Jewish science, Byzantium and pre-Columbian America. Geographical unity is maintained not only by description of transcultural influences, but also by some comparative discussion of method and scientific attitude. This is especially valuable in the case of Chinese science, which started so promisingly but scarcely came to theoretical fruition, and is admirably done in the space of two short chapters by A. Haudricourt and J. Needham.

The further subdivision of each cultural unit is generally into the various special sciences, with more extensive attention to medicine than is usual in such works. In the case of the Greeks, the unity is rightly seen as one of philosophical school rather than of subject-matter, and a sustained exposition in four chapters of Greek science and mathematics from Thales to Aristotle by P.-H. Michel provides a firm centre-piece for the book, for subsequent specialized developments took their origin from this period. Indeed, fundamental views of the nature of scientific knowledge, and theories of the structure of matter and the cosmos, continued until the seventeenth century to be directly indebted to the conflicting philosophies of Democritus, Plato and Aristotle. It is good to see in a volume of this kind a proper place given to philosophical influences, and particularly to the Platonic tradition, which has often been denigrated by historians of science. But since the monumental researches of Alexandre Koyré and other students of Renaissance and seventeenth-century science, no historian can ignore the vast influence of the Platonic mathematization of Nature, which can be regarded as one of the major sources of the science of Copernicus, Galileo, Kepler and Descartes. Within the book's brief compass, full value is given to the continuity discerned by recent historians between ancient and modern science.

How successful is the volume in its aim of introducing history of science into the general historical perspective of the educated man? In spite of many good things, one must still confess to some doubts as to whether the method of approach is the most suitable for this purpose. There is a serious attempt in many of the sections to relate the details of scientific development to their cultural background, as well as to face squarely the question how far this was 'science' in any sense we would now recognize. A fairly coherent view emerges among the various authors as to what we do in fact recognize as the essentials of science. This is an empiricism somewhat modified by theoretical systematization: "The true scientist joins accurate knowledge of the facts to the demands of reason" (p. 258), and examples of mere observation or technique without rational system are condemned as pre-scientific. But there are still too many phrases which echo an earlier and less satisfactory style in the historiography of science: "In Galen's physiology we must distinguish between far-fetched biological theory and brilliant individual discoveries" (p. 359) is one example among many. The implication is that theories ought not to be far-fetched, and that discoveries are independent of theories. But what could have been more far-fetched in their historical context than Newton's action-at-a-distance, or Einstein's curved space-time? And what discoveries would have been made without the aid of these conceptions? The historian's besetting temptation is to condemn earlier science because it turned out to be 'false', instead of judging it according to the evidence available and the criteria recognized in its day. The brevity of the general discussion of historical background which is dictated by the scope and form of this book makes it difficult for many of the authors to guard against such distortions. It is flattering to our self-esteem to look to the distant past and to think we recognize faint premonitions of our own science among much wrong-headedness in the best intelligences we find there, but a deeper historical insight will often reveal that they shared few of our interests, criteria or values, and to a modest historical view they are not necessarily the worse for that. All of which leads one to wonder whether the cause of history of science is not better served by works of general history devoted to more limited periods and cultures, which show science, philosophy and technique as integral parts of a context developed in terms of its own values in more detail than is possible here.

If the project does not quite succeed in giving historical significance to the science of the distant past, it is nevertheless a unique mine of information, beautifully illustrated, and exceptionally well translated.

MARY HESSE

TECHNIQUES IN ENDOCRINE RESEARCH

Techniques in Endocrine Research

Edited by Peter Eckstein and Francis Knowles. (Proceedings of a NATO Advanced Study Institute held at Stratford-upon-Avon, England, under the auspices of the University of Birmingham.) Pp. xvi+319. (London: Academic Press, Inc. (London), Ltd.; New York: Academic Press, Inc., 1963.) 63*s*.

IN September 1962 a meeting on the techniques used in endocrine research was held at Stratford-upon-Avon under the auspices of the North Atlantic Treaty Organization. Most of the papers which were read are now published in book form.

The volume consists of communications dealing with the following topics: X-ray crystallography (D. C. Hodgkin); hormone-containing sub-cellular particles (U. S. von Euler); antibody staining techniques (F. A. Pepe); neurosecretion (F. Knowles); ultrastructure of the mammalian pituitary (R. L. Holmes); autoradiography (A. Ficq and J. Flament-Durand); chromatography (E. Lederer); hormones in blood (H. N. Antoniades); immunochemical methods (R. G. White); interpretation of biochemical techniques (R. B. Pennell); the experimental animal (W. Lane-Petter); the pituitary complex (J. M. Dodd); hormones and gene action (P. Karlson); transplantation (P. L. Krohn); preservation and storage of endocrine tissue (A. S. Parkes); purified protein hormones in human endocrinology (C. Gemzell); endocrinology of reproduction (M. C. Shelesnyak); ovum implantation (G. Mayor); hormones in development (A. Raynaud); trends in methodology (M. Klein).

It is unfortunate that not all the participants were able to present written accounts of their papers for publication. This omission is, however, not so important to the reader as the failure to include the discussion which followed each communication. In the form in which it is published, *Techniques in Endocrine Research* thus presents a series of discrete papers rather than an integrated account of the subject as a whole. The inclusion of the discussions might well have overcome this defect, as well as providing further insight into the problems associated with the methods discussed. A less-important factor, but one which detracts from the value of the book as a whole, is the inadequacy of the subject index. Thus, to give one example, in her paper Dr. Hodgkin discusses the X-ray crystallography of insulin in some detail, but there is no mention of this in the index. This means that although the book can be used as a reference work, it will be of greater value to peruse the relevant chapters in detail.

The value of the book lies in the fact that it consists of the description of a wide range of techniques at present used in endocrine research. In the introduction Sir Francis Knowles reminds us that "developments in physics and chemistry during the past thirty years have revolutionised biological research". Approximately half the papers included in the volume are devoted to illustrating this point. The relevant communications generally consist of a brief historical introduction followed by a more detailed discussion of the recent applications of a particular technique to endocrinology. Most of the remaining chapters deal with the interrelationship or application of a variety of procedures to a given problem. This is well illustrated in the chapter by Dr. Shelesnyak, which describes the way in which biological and chemi techniques have been used to investigate the mechani of nidation.

Laboratory animals have been used extensively experimental work throughout this century. It is, ho ever, only relatively recently that the well-being of t animal has been considered. Because of this fact, t inclusion of a paper by Dr. Lane-Petter on the expe mental animal in research is very welcome.

A large number of different experimental techniques a described and it would, therefore, be inappropriate discuss any particular method in detail. In view of t many specialized technical journals in which such metho are published, the value of the book to the chemist and the biologist is considerable, in that it provides descriptio of both recent and classical methods in endocrinolog This volume may, therefore, be recommended with co fidence for perusal by anyone interested in endocrinolog

E. TREVOR BELL

RADIATIVE TRANSFER IN THE U.S.S.R. AND THE WEST

A Treatise on Radiative Transfer

By V. V. Sobolev. Translated by Dr. S. I. Gaposchk Pp. xi+319. (Princeton, N.J.: D. Van Nostrand Co pany, Inc.; London: D. Van Nostrand Company, Lt 1963.) 76*s*.

THE development of the theory of radiative trans during the years 1940–60 proceeded in the U.S.S. and in the West along roughly parallel lines, but until t past few years of the period contacts were few. Weste astrophysicists were strongly influenced by the work S. Chandrasekhar, while Russian astrophysicists f lowed V. A. Ambartsumian and V. V. Sobolev.

It is sobering to read this translation of Sobole treatise, first published in 1956, and to realize th methods which were only then being developed in Weste journals had been in use in the U.S.S.R. for some yea The comparison and appreciation of results and metho were made more difficult by the use of different notatio for standard functions. Thus, Chandrasekhar a Western writers used, and still use, $H(\mu)$, $X(\mu)$, $Y($ where Sobolev and the Russians used $\varphi(\eta)$, $\varphi(\eta)$, $\psi(\eta)$, notation which has been adhered to in the translation.

For an experienced astrophysicist, *A Treatise on Rad tive Transfer* is an exciting book, but unfortunately it w be of little value to a beginner until a corrected version available. Many misprints have come from the origir Russian version, while others have been introduced by t translator or the printer. On p. 65, for example, the on formulæ without some sort of omission are (46) and (4 The translation itself is sometimes misleading. Thus, p. 110, in the sentence "Let us consider the transmissi coefficient only for the case of the spherical scatteri indicatrix", 'only' should be 'also' and 'spherical' should 'non-spherical'.

When the difficulties caused by misprints have be overcome, the reader will find much to interest hi Sobolev first develops most of the known methods dealing with transfer problems. Special mention mu be made of the so-called probabilistic method, d originally to Sobolev, which is based on the probabili that a quantum absorbed at depth τ below the surfa will leave the medium in a certain direction. The methods are applied to various physical problems, su as the scattering of polarized light in planetary atm spheres and in the electron atmosphere of a star; t luminescence of a medium bounded by a reflecting surfa light scattering when there is a redistribution in frequen and the consequent effect on the contours of absorpti lines; and non-stationary radiation fields.

It is in the detailed applications of general results that Sobolev's book will most delight the experienced reader. Besides applications to planetary atmospheres and nebulæ, one finds a discussion of the brightness of an overcast sky at sea allowing for reflexion of light by the sea, and the brightness of the sea itself allowing for both reflexion from the surface of the sea and scattering of light in the sea. In the final chapter, Sobolev uses transfer theory to explain why a flat fish, in order to be nearly invisible, is white below and dark above!

Much perplexity has been caused in recent years by the non-uniqueness of the solutions of some of the integral equations of transfer theory. These problems have now been cleared up, mainly through the recent work of T. W. Mullikin in the United States. Sobolev has nothing much to say about existence and uniqueness of solutions, but happily he has selected the best function whenever a family of solutions exists. This makes his book valuable as a basis for future work.

Dr. S. I. Gaposchkin is to be thanked for making Sobolev's book available to Western astrophysicists. He has himself added to the book some of Sobolev's latest articles, adapting them slightly so that they fit in with the book. Thus the version in English is an enlargement of that in Russian.

I. W. BUSBRIDGE

LAND AND WATER USE IN THE UNITED STATES

Land and Water Use

Edited by Wynne Thorne. (A Symposium presented at the Denver Meeting of the American Association for the Advancement of Science, 27–29 December, 1961.) (Publication No. 73.) Pp. x + 364. (Washington, D.C.: American Association for the Advancement of Science; London: Bailey Bros. and Swinfen, Ltd., 1963.) 80*s*.

LIMITED land and water resources in relation to present and future population is a problem which confronts not only Britain but increasingly other parts of the world. Not least of these areas is the United States, and although the problems in this case are on quite a different scale from those confronting Britain much can be learnt from the study of somewhat similar situations in other localities. This new publication of the American Association for the Advancement of Science is therefore especially welcome for it summarizes a symposium which took place at the Denver, Colorado, meeting which had as its objective a consideration of land and water as related resources with special reference to the mountain and plains region of the United States—wherein we find concentrated many of the United States' most critical problems of land and water use.

Whereas most of the plains region is now in private ownership, more than half the inter-mountain area remains in Government hands. Competition for the region's resources brings about pressures on both the private and public sectors for courses of action which are often conflicting. The symposium was therefore largely concerned with a consideration of many of these conflicting claims and an attempt is made to evaluate the long-term consequences of the application of selected policies.

Contributors to the symposium were drawn from many disciplines and organizations and were carefully selected as individuals who could talk authoritatively concerning these basic natural resources. The scene is set by an introductory chapter on "Land and Water Use" by Wynne Thorne, who edits the collection of papers. This is followed by a group of articles under the collective title of "The Resource Setting", the topics included ranging from population demands on land and water, potential uses, livestock interests, public grazing, evaluations of dryland environments at differing technical levels, recreation as a competitive segment of multiple use, management and vegetation of watershed areas, hydroclimatology, to methods of securing additional water supplies.

Part 3 deals with "Criteria and Policies", with chapters on economic priorities for water use in arid regions, management of wildlands, multiple use in the management of land and water, and criteria and planning for optimum use. Part 4 covers the role of Government in seeking solutions to the problems which lie ahead, with contributions on wilderness problems, public and private investment in development, and legal aspects of a national water programme and a concluding chapter on "Government Responsibility for Land and Water—Guardian or Developer?".

It will be clear that the symposium is wide-ranging and comprehensive and that it touches on many points. Throughout, however, there is a significant repetition of references to the concepts of multiple-use and optimum-use. Specialists in the field of resource management argue that the concept of multiple-use provides the most practical approach in seeking maximum benefits from land resources. Management for multiple-use is based on human value systems and fulfils human needs by increasing total useful production. It is argued that such policies should be flexible enough, however, to serve the future welfare of the nation. Recreational uses are vital but difficult to evaluate financially.

Others have argued in favour of the concept of optimum-use since the concept of multiple-use has limited value as a basis for determining public and private policies in planning and management. But a determination of optimum-use requires extensive research on resources and better criteria for estimating exactly what would be the optimum-use in particular cases. A complete inventory of all land resources would in fact be necessary before foolproof decision-making on optimum-use becomes possible.

It is the responsibility of Government to assure the maximum benefit to the country of the available resources with particular reference to the 'public good'. But it is important to remember that financial statistics cannot always be used to evaluate competing interests. A recreational national park cannot be judged by its turnover of "hot dogs, fishing tackle and gasoline sales"; its true worth cannot really be measured in any financial terms.

Among the major recommendations which emerge from these papers are: (1) the need for a detailed inventory of water and land resources evaluating specific characteristics; (2) the need to place æsthetic enjoyment and leisure time use in balance with economic demands; (3) the need for a clearer definition of governmental responsibilities and functions in relation to land and water resources; (4) the need for policy criteria to guide future governmental actions.

It will be clear that most of the principles discussed in this important symposium are immediately relevant to the problems which Britain faces in the proper use of land and water resources. The concepts of multiple-use and conservation are slowly gaining ground together with a need for a detailed inventory of water and land resources. Government, however, moves but slowly and Britain has not yet reached the stage where land utilization survey has become a regular and official activity for the whole country. Meanwhile we have to rely on the private enthusiasm of dedicated geographers. Adequate data on water resources should, however, be forthcoming once the Water Resources Act, 1963, has been brought into full force. As the pressure of population on both land and water amounts with increasing numbers and increasing leisure the community will be forced into undertaking more detailed inventories of both water and land resources, of resolving the problems of multiple-use as against optimum-use, and of accepting the need for more Government action. This symposium from the United States makes valuable background reading for all those concerned with finding the solution to the problems that are approaching all too rapidly.

W. G. V. BALCHIN

Annual Review of Nuclear Science

Volume 13. Edited by Emilio Segre. Pp. vi+590. (Palo Alto: Annual Reviews, Inc., 1963.) 8.50 dollars.

THE mixture as before comes from Annual Reviews; one dozen assorted articles on various aspects of nuclear science. No one will want to read them all, but each will be interesting and useful to many. This kind of review tends to remain a standard reference for several years.

In the field of nuclear reactions, Glendenning discusses stripping at considerable length, while Stelson and McGowan survey Coulomb excitation more briefly. In high-energy particle physics, Puppi and Dalitz deal with the pionic and strange-particle resonances, respectively. As usually happens with such reviews, several new particles have appeared while they were in the press, but Dalitz has partly insured against this risk by discussing the predicted Ω^-. The surprise particle of two years ago is covered by Feinberg and Lederman, in a paper on the muon and the muon neutrino.

There are two correlated papers on the slowing-down of charged particles in matter; Fano deals with protons, α-particles and mesons, while Northcliffe takes the rather different case of heavy ions. Cumming contributes a review of data and techniques used for monitoring high-energy proton beams. The automatic analysis of bubble chamber data is a new technology; Rosenfeld and Humphrey tell the inside story, full of evocative code-names—*Franckenstein* is a machine, *Quest* and *Fake* are computer programmes.

Finally, there are three shortish surveys representing some other sciences in the nuclear field. Sayre summarizes the methods and uses of activation analysis, Björnerstedt and Edvarson describe some questions needing further research in the physics, chemistry and meteorology of fall-out, and Hutchinson writes about the effects of radiation on biological macromolecules.

On the whole, these reviews are meant for serious students and research workers in the subjects concerned, but several of the shorter ones will interest the casual onlooker who simply wants to widen his horizons. This volume is a worthy continuation of a useful series.

R. J. N. PHILLIPS

Atomic Structure and Chemical Bonding

A Non-Mathematical Introduction. By Fritz Seel. Translated from the Fourth German edition and revised by N. N. Greenwood and H. P. Stadler. (Methuen's Monographs on Chemical Subjects.) Pp. vii+112. (London: Methuen and Co., Ltd.; New York: John Wiley and Sons, Inc., 1963.) 15*s*.

THE translation of Prof. Seel's *Atombau und Chemische Bindung* by Prof. Greenwood and Dr. Stadler makes readily available to English students a monograph which has proved very popular in Germany. It provides an introductory treatment in non-mathematical terms of the theory of chemical bonding, being concerned with the development of principles underlying the whole of chemistry without arbitrary sub-division. Undoubtedly students will appreciate the clear synoptic view of the subject which it develops clearly and concisely. Not only are the more conventional aspects of bonding theory introduced descriptively but these ideas are also very widely applied. Having developed the theory underlying the formation of molecules and crystals the author provides a discussion, supported by pictorial models, of material ranging from stereochemistry and chemical reactivity, over intermetallic compounds and electrical conduction to the strength of materials and the elasticity of rubber. This coverage in a small book is achieved only as the result of a very concise style of writing. In places the material is condensed to the point of terseness, and a student will probably gain little here, if this is his first encounter with the ideas, although he might well find it useful in providing perspective in the area after making a more detailed investigation.

Some parts of the book can be criticized for over-simplification. The directions of chemical processes are discussed without reference to entropy changes and in one place relative rates of two reactions are accounted for by writing seven versus six resonance structures for the transition state. Ideas are frequently introduced rather loosely: "The electron in each cell traces out a particular pattern or *orbital* . . ." serves to define an orbital; transition state is introduced by referring to "the energy level of the *transition state*".

More seriously, it seems a pity that some feeling for the relative strengths of chemical bonds is not developed. The book is weak generally on energetics; there is little on lattice energies, almost nothing on solvation energies and bond energies are not mentioned.

The great merit of the book is the way in which it relates bonding theory to chemistry at a simple descriptive level. It can confidently be recommended as a stimulating introduction to the subject.

D. J. MILLEN

Introduction to the Constructive Theory of Functions

By Prof. John Todd. (International Series of Numerical Mathematics, Vol. 1.) Pp. 127. (Basle and Stuttgart: Birkhäuser Verlag, 1963.) 27.50 Sw. francs.

THE constructive theory of functions deals with approximations to a given function in terms of simple elements, such as polynomial approximation to a continuous function in a basic interval, or approximation to a periodic continuous function by trigonometric polynomials. It is, therefore, a well-defined field of mathematical analysis, which may serve as a theoretical basis to much recent work on numerical methods.

Weierstrass's fundamental theorem, that a polynomial can be found which will not differ from a given continuous function over a finite interval by more than a prescribed ε, leads us at once to ask what may be meant by a 'best' polynomial approximation, and how, when defined, it may be found. Here the Chebyshev polynomials which, of all polynomials in $(-1, 1)$ with leading coefficient unity, deviate least from zero become relevant, and this book gives a very concise but reasonably comprehensive table of the main formal properties of these and of other orthogonal polynomials arising from a suitable weighting of the mean square error. The Bernoulli polynomials are discussed so far as is needed for dealing with the Euler–Maclaurin summation formula. A brief chapter on interpolation stresses, by means of exercises, the simplification, due to A. C. Aitken, which reduces n-point interpolation to successive linear interpolations. The concept of 'best' approximation is generalized by the use of function spaces, enabling a discussion of existence and uniqueness to be given in economical form. Finally, numerical integration is briefly developed on a Gaussian basis.

The text, apart from the solutions to the exercises, takes up only ninety pages, so the large amount of ground covered necessitates a terse exposition. The author demands full co-operation from the reader, but shows remarkable skill in emphasizing the key-points of an argument, so that the conscientious reader should never have any difficulty in filling in details. There are about 100 exercises, with solutions; some develop more fully matters which are briefly sketched in the main text, others arise fairly from the text but seldom degenerate into points of routine drill. Obviously much care has gone into the construction of these problems, and a young student could scarcely fail to find his curiosity strongly stimulated. The book reads as if the author had thoroughly enjoyed writing it, which should encourage many students to enjoy reading it. The new series of texts on numerical mathematics is off to a flying start.

T. A. A. BROADBENT

FOUNDATIONS OF QUANTUM MECHANICS

By Prof. P. A. M. DIRAC, F.R.S.
St. John's College, Cambridge

In view of the profound difficulties met with in quantum field theory the foundations of quantum mechanics, which were established more than thirty years ago, are under suspicion. Let us re-examine these foundations and see if they can be amended.

Quantum mechanics, as introduced by Heisenberg in 1925, involved dynamical variables u which do not obey the commutative axiom of multiplication and which satisfy the Heisenberg equation of motion:

$$i\hbar\, du/dt = uH - Hu \tag{1}$$

where H is the Hamiltonian. These dynamical variables were first represented by matrices. Later it was found that they could be considered as operators operating on the vectors of a Hilbert space. It is convenient to denote the Hilbert vectors by symbols such as $|A)$ and the result of applying a dynamical variable u to $|A)$ by $u|A)$.

Shortly after Heisenberg's discovery, another quantum theory was discovered independently by Schrödinger, based on different ideas. Here the emphasis was on physical states, represented by wave functions. The wave functions may be considered also as vectors in Hilbert space, so they may also be denoted by symbols $|A)$. They differ from Heisenberg's Hilbert vectors in that they vary with the time, in accordance with Schrödinger's wave equation:

$$i\hbar\, d|A)/dt = H|A) \tag{2}$$

while Heisenberg's were constant.

For a while physicists had two quantum theories to work with; but it was soon proved that there was a simple connexion between them, resulting in their being equivalent. The Hamiltonian H is the same operator in both theories. The dynamical variables and the Hilbert vectors in the two theories are connected by a unitary transformation:

$$u_S = e^{-iHt/\hbar}\, u_H e^{iHt/\hbar}, \quad |A_S) = e^{-iHt/\hbar}|A_H) \tag{3}$$

where the suffixes S and H refer to Schrödinger and Heisenberg respectively. Thus there was just one quantum mechanics with two ways of looking at it, Heisenberg's picture and Schrödinger's picture.

This quantum mechanics had enormous success when applied to the simpler problems of the atomic world, but ran into serious trouble when one tried to set up an accurate relativistic theory involving fields. The trouble was most acute for electrodynamics, because the other atomic fields were not very well known and one could ascribe the difficulties for them to our imperfect knowledge of the forces involved. But electrodynamics was so well understood classically that it was most puzzling to find that quantum theory fails for it.

To focus our attention on the trouble, let us put it in its simplest form. Let us confine our attention to electrons and positrons interacting with the electromagnetic field. Then it is not difficult to obtain the Hamiltonian H. One can be confident that this H is essentially correct because, when one uses it in the Heisenberg equations of motion (1), one gets sensible field equations in agreement with what one would expect from classical electrodynamics. However, when one inserts this H into Schrödinger's wave equation (2), one cannot find any solutions, not even approximate ones. Presumably solutions do not exist. Physically, one would expect there to be a trivial solution corresponding to the vacuum state, but there is not even this trivial solution.

We have here the dilemma which has hindered the development of theoretical physics for three decades. There is a simple way out of it. Evidently the Schrödinger picture will not work at all, but the Heisenberg picture is not so bad. We may consider that: *The Heisenberg picture is a good picture. The Schrödinger picture is a bad picture. The two pictures are not equivalent.*

The reader will immediately say, "What about the proof that the two pictures are equivalent ?". Let us examine this proof and see if it is sound. It involves a unitary transformation to connect the two pictures, in accordance with (3). The unitary transformation exists, of course, only if the operators $e^{iHt/\hbar}$, $e^{-iHt/\hbar}$ exist. Now the H with which we are dealing is quite a complicated operator, and it is not immediately evident that exponentials of it should exist. We may check whether $e^{-iHt/\hbar}$ exists from first principles, taking a definite Hilbert vector $|B)$, say, and seeing whether $e^{-iHt/\hbar}|B)$ then exists. If it did exist, we see at once that it would be a solution of the Schrödinger equation (2). But such solutions do not exist. Hence the operator $e^{-iHt/\hbar}$ does not exist and the proof of the equivalence of the two pictures fails.

Let us make a closer examination of the two pictures to see the advantages of Heisenberg's. In electrodynamics one may treat the interaction between the particles and the electromagnetic field as a small perturbation, and can then seek a solution of the equations in powers of $e^2/\hbar c$.

If one tries to solve the Schrödinger equation on these lines one gets an expansion, each term of which corresponds to a Feynman diagram. All the terms except the first few involve divergent integrals. Among the terms there are some that correspond to v–v (vacuum to vacuum) transitions with no external lines in the Feynman diagrams. These terms are the worst ones. They prevent one from getting a solution to represent the vacuum state. The divergent integrals in the remaining terms can be dealt with by the technique of re-normalization.

One may try to solve the Heisenberg equations of motion by a similar perturbation method. One then gets an expansion, the terms of which again correspond to Feynman diagrams, with similar divergent integrals. But there are now no v–v terms. The reason for the difference is that, if one starts with zero in the Heisenberg picture, it remains zero, while if one starts with the vacuum in the Schrödinger picture, it does not remain the vacuum. In this way the Heisenberg picture avoids the worst difficulties of the Schrödinger picture. Those that are left, the divergent integrals in the non-v–v terms, can be tackled by limiting processes corresponding to re-normalization.

In the Schrödinger picture the perturbation is so violent that, if one starts with a particular Hilbert vector to represent the initial state, *it gets knocked right out of Hilbert space* in any time-interval, however short. The v–v terms are responsible for this. With such a violent perturbation the Schrödinger picture is unworkable.

In the Heisenberg picture there are no such violent reactions. However, the Heisenberg dynamical variables can no longer be taken to be operators in Hilbert space. They must be something more general, the precise nature of which is at present unknown. We may call them q-numbers. All that is known about them is that they are non-commuting quantities satisfying definite commutation relations. Calculations in the Heisenberg picture consist of algebraic deductions from the commutation relations, which one performs without knowing the mathematical nature of the quantities with which one is working.

The foregoing discussion shows that one should establish quantum field theory entirely in the Heisenberg picture, with all references to the Schrödinger picture cut out. We now have the big problem of setting up a method for the physical interpretation of the results of calculations in the Heisenberg picture. The usual interpretation of quantum mechanics involves the Schrödinger picture, the square of the modulus of the wave function being interpreted as a probability, and so cannot be used. I propose the following new interpretation.

Each physical state throughout all time corresponds to a solution of Heisenberg's equations of motion. This is a q-number, K_t, say, a function of the Heisenberg dynamical variables at time t containing t also explicitly, which is a constant of the motion, so that:

$$\frac{dK_t}{dt} = \frac{\partial K_t}{\partial t} + [K_t,H] = 0$$

For each value of t, K_t will be a function of the emission operators η_t of various particles and the corresponding absorption operators $\bar{\eta}_t$ and also of t explicitly. We suppose the q-numbers can operate on vectors $|A)$ of a more general kind than Hilbert vectors. For each time t we set up a vacuum vector $|V_t)$, satisfying $\bar{\eta}_t|V_t) = 0$ for all absorption operators $\bar{\eta}_t$. Then we can interpret $K_t|V_t)$ like the wave function at time t in the old theory. We may express K_t as a sum of terms each having all the η's to the left of all the $\bar{\eta}$'s. Those terms that contain $\bar{\eta}$'s will give zero when multiplied into $|V_t)$. The coefficients of the remaining terms will then be physically significant, the squares of their moduli giving the probabilities of various particles being present at the time t.

It will be seen that, so far as concerns conditions at one instant of time, the new interpretation corresponds exactly to the old one, with $|V_t)$ representing the vacuum state and $K_t|V_t)$ a general state. Under variations of t the new theory is quite different, since $|V_t)$ is not a solution of the Schrödinger equation, nor is $K_t|V_t)$. The most striking departure from the old theory lies in the fact that the quantity $K_t|V_t)$, playing the part of the wave function at time t, does not fix the quantity $K_{t'}|V_{t'})$, playing the part of the wave function at time t', since one may have $K_t|V_t) = 0$ for a particular t without having $K_t = 0$, and thus without having $K_{t'}|V_{t'}) = 0$. There is no longer determinism for the wave function, as in the Schrödinger theory, but only determinism for the q-number K_t.

The usual formulation of quantum electrodynamics is a set of working rules and is not a logical deduction from the general principles of quantum mechanics. It has had great success in giving correctly the Lamb shift and the anomalous magnetic moment of the electron.

We may now formulate quantum electrodynamics as a logical deduction from Heisenberg's quantum mechanics with the foregoing physical interpretation. This leads to the same results for elementary problems of radiative transitions, the calculations being essentially the same as before, except that the v–v terms of the interaction automatically drop out and no longer have to be arbitrarily discarded. I have checked that the new theory leads to the correct Lamb shift and anomalous magnetic moment for the electron, to the order of $e^2/\hbar c$. Thus the successes of quantum electrodynamics can all be maintained with the increased standard of logic that the new formulation provides.

In conclusion, I would like to say that the development of quantum theory proposed here should not be considered as detracting from the value of Schrödinger's work. The Schrödinger picture is a very good one for all those problems in which only a finite number of degrees of freedom are effective, such as problems in which the electromagnetic interaction can be represented by Coulomb forces, and it will continue to be used extensively as it is then simpler and more convenient than Heisenberg's. Only when one goes to an infinite number of degrees of freedom does one find that the Schrödinger picture is inadequate and that the Heisenberg picture has more fundamental validity.

GREY SEALS AND FISHERIES

By Dr. E. B. WORTHINGTON

Deputy Director-General (Scientific), Nature Conservancy,
19 Belgrave Square, London, S.W.1

In July 1955 the Nature Conservancy was asked by the Ministry of Agriculture, Fisheries and Food to advise on the problem of damage caused to fisheries by grey seals (*Halichoerus grypus*). The complaints were mainly from south-eastern Scotland near the mouth of the River Tweed, whereas the seals alleged to be troublesome were assumed to come from the Farne Islands, south of the border.

At that time there was not much scientific knowledge about the grey seal or its relation to fisheries. Several biologists had investigated aspects of its natural history, behaviour, breeding biology and population structure in Cornwall, Pembrokeshire and the Hebrides[1-6]. In 1951 Hickling[7] had begun marking young seals on the Farne Islands to trace their movements in the sea, but accurate counts of the breeding population there were not started until 1956. However, the challenge was accepted, and two years later Lockie[8] had made a preliminary investigation of the damage caused on the Northumberland and Berwickshire coast. With this rather scanty background, the Nature Conservancy advised that, in addition to initiating a programme to discover means of protecting nets against seals, the Ministry should, as an experimental and interim measure, limit further increase of the Farne Islands colony by conducting an annual cull of calves.

Although population control on any significant scale was not in fact undertaken at that time, research on many aspects of the situation was augmented. In addition to continuation of work by Hickling on the Farnes, and by Lockley in Pembrokeshire, annual visits to North Rona were started by Boyd[9] and his collaborators. In 1959 a Consultative Committee on Grey Seals and Fisheries was set up by the Development Commission and the Nature Conservancy. E. A. Smith was appointed as seal research officer and has already presented results on a number of aspects of the problem, in the Committee's Report[10]. He has also investigated grey seals in other parts of their distribution range, during visits to north-east Canada, Norway and the Baltic. One of the few remaining areas where little is yet known about the status of the species, around the Irish Republic, will be studied in the next year or so.

On the much-debated question of the influence of grey seals on fisheries, Rae[11] described the kinds of damage caused. Seals are frequently seen near salmon nets and have been observed killing and eating salmon. Regular recordings of the presence of seals at fixed-net fishing stations have been made over the years 1959–63; these results have been analysed by Rae and Shearer, of the Scottish Fisheries Department, who will soon publish their report. The records of a representative sample of salmon packing stations indicate that at least 6 per cent of the total catch of salmon bear seal claw or tooth marks. Fish, evidently mutilated by seals, are frequently found in nets or washed ashore near by. Almost all fixed-net stations on the Scottish coast suffer damage to nets; during the period 1959–61, the average number of nets damaged by seals was 10 per cent of the total fishing effort.

The fishery for cod and other white fish also suffers damage from seals; but it is less easy to assess this quantitatively than in the fishery for salmon and sea-trout. However, the organization now exists for collecting data on seal damage in a form which is susceptible to statistical analysis.

As a result of these investigations, many of which are still in progress, it can be claimed that there is a much better scientific background for attempting to solve the seals/fisheries problem to-day than there was nine years ago when it first came into prominence. Some of the salient results can be summarized as follows:

The world population of grey seals is now estimated at about 46,000 all but 10,000 of which live around the British Isles. Recent censuses during the breeding season have shown some 10,000 to be based on Orkney and 3,500 on the Farne Islands. In the early years of the century, before the Grey Seal Protection Acts of 1914 and 1932, the species was thought to be so rare as to be in danger of extermination, although valid evidence for that opinion is now difficult to find.

The rate of increase of population is best illustrated by the Farne Islands, where there are several early estimates and since 1956 detailed counts of calf production[12]. These show an overall annual rate of increase since 1956 of more than 7 per cent, which implies doubling of the population in less than ten years. Some of the Farnes breeding beaches are densely crowded, with calf mortality sometimes as high as 20 per cent; but there is no evidence as yet of a flattening of the population curve. In recent years small breeding groups have become established on the Scroby Sands and Isle of May. It may be significant that Scroby, where the colony would appear to be an overflow from the Farne Islands, is the only place where grey seals are known to breed on a sand bank.

The grey seal population of North Rona seems also to have undergone a rapid increase. It is fairly certain that none bred there until the human population was evacuated in 1844. In the 1880's, 100 or so were killed each year. In 1939 Fraser Darling estimated that 1,500 pups were born there, which indicates an adult population of rather more than 5,000. Counts by Boyd and his collaborators put it at more than 9,000 to-day. No other colonies have records adequate to estimate increase in population, but Orkney in 1960, the first year of census, had far more seals than had previously been thought. The only major colony where it would seem that the population has not increased markedly is around Shetland, where a tradition of seal hunting has persisted throughout the years and the shore habitats are for the most part unsuitable.

Longevity has been established through reading the age of seals from tooth sections. The oldest bull so far examined from British waters was 23 years and the oldest cow 35 years. Females are capable of conception from the age of 5 years and sexual maturity is attained in males at 6 years, although the successful maintenance of breeding territories appears to be restricted to bulls between the ages of 10 and 20 years. Facts such as these, observations and counts at breeding grounds, the study of post-mortem material, and comparisons with other species of pinnipeds the biology of which is better known have enabled Hewer[13] to prepare a provisional life-table of the species.

Exact information about the movements of grey seals in the sea is so far limited mainly to their first year, because no tag has yet been devised which will remain attached to the animal for much longer than that. In all some 3,300 young seals have been tagged on the breeding beaches of the Farne Islands, 1,700 on Orkney, 1,100 on North Rona and 1,200 in Pembrokeshire, with smaller numbers in the Hebrides and Shetland. Occasional recoveries have come from as far away as north-west Ireland, Norway, Iceland, Holland and Spain, but the general pattern of returns shows a rather uniform dispersal from the points of origin with no obvious drifts or bias in particular directions. In the region where damage to fisheries is reported as most intense, from Durham northwards to Caithness, a large proportion of young seals come from Orkney or the Farnes. It seems probable that the older seals distribute themselves in a similar pattern to the young ones; definite information about them should become available before long, since a substantial number of seals from North Rona and Orkney are now carrying brand marks which last much longer than tags.

The food of grey seals is known at present only from about 200 stomach examinations. Animals eaten range widely, with salmon and sea-trout, cod, plaice, sand eels, squid and crab among the more prominent. It is clear that seals, like fishermen, are opportunists, so when fisheries are operating at a maximum, seal activity is also greatest in the same area. Hence the apparent anomaly that complaints of damage are apt to be greatest when the fisheries appear to be most prosperous.

The incidence of cod-worm (*Porrocaecum decipiens*) is a matter of concern to the white fish industry. Rae[14] has examined the incidence of the larvæ, of which the grey seal and to a lesser extent the common seal are definitive hosts, and as such necessary for the worms' full development. He presents much evidence that a big increase in the proportion of infested cod in some areas is associated with the increase in the number of grey seals.

The Consultative Committee on Grey Seals and Fisheries[10], having considered all this and other evidence, and taking all interests into account—the fishing industry, the naturalists and the seals themselves—reached the conclusion that some control of the seal population was necessary. The Committee recommended, however, that such control should be limited to the two colonies which, from the marking experiments, were suspected of doing a large proportion of the damage to the vulnerable fisheries of the east coast of Scotland and northern England. It would not be sufficient to take from these two colonies an annual crop equivalent to the estimated annual gain, but some inroads should be made into the future breeding potential, provided such could be achieved without endangering the continuation of these colonies in flourishing condition.

It was decided that the aim should be to reduce the breeding potential of both these colonies by 25 per cent in the course of five years. Assuming that the Orkney colony has been increasing at approximately the same rate as that on the Farnes, such a reduction would bring the numbers of each colony down to what they were in 1959. It was appreciated, of course, that such a reduction would not meet the demands of the fishermen; but the Committee thought that a modest reduction in the number of seals, coupled with continued efforts to scare seals away from the fishing centres and the use of more resistant nets, was likely to reduce the damage to tolerable limits in years to come.

This general recommendation by the Consultative Committee, which is supplemented by detailed proposals made from year to year in the light of experience and of continuing research, was endorsed by the Nature Conservancy and accepted by the Ministry of Agriculture, Fisheries and Food and the Secretary of State for Scotland. After the appropriate orders had been laid before Parliament, the proposed culling operation was carried out by the Ministry of Agriculture, Fisheries and Food on the Farnes during the seal breeding season of 1963, and the operation in Orkney was arranged by the Department of Agriculture and Fisheries for Scotland in 1962 and 1963.

It is important to note how this unpopular work was carried out, because in the process evidence was collected which will help to ensure the sensible management of grey seal populations in future years. In the Farnes the culling was done during three days in December 1963 by agents of the Ministry in a well-planned operation. The number needed to achieve the object was 85 adult cows with their calves, or, failing that, 360 female calves, or a combination of the two. In the circumstances prevailing, with a good many onlookers, it was difficult to take adults cleanly and safely, so the cull was limited almost entirely to calves, the bodies of which were removed immediately for disposal of the products. An important result was that the operation was performed without any hint of cruelty and the survivors took remarkably little notice, as described by Hickling[15]. This, together with comparable experience from Orkney, provides a reassurance that management of these seal populations can be undertaken without the risk of upsetting the breeding biology through disturbance.

In Orkney, licences were issued by the Department to a number of local men. Since under such arrangements it would be impossible to limit killing to females, substantially larger numbers would be needed to achieve the object. The calculations showed that approximately 1,800 calves would be required annually, four calves being the equivalent in this context to one adult. However, since there were unknown factors in this operation, the Committee thought it wise to err on the safe side and recommended that the numbers killed in each of the two seasons 1962 and 1963 be limited to 750. In 1962 the returns did not exceed this figure, but in 1963 the number had reached 974 before licences could be withdrawn.

Following a wide ventilation of the pros and cons of controlling the numbers of this species, in the newspapers, on television, and in sections of the scientific Press, we now move forward to the third year of the proposed operation on Orkney and the second year on the Farne Islands.

The philosophy of controlling populations of wild animals, even those living in nature reserves, has been well described by Fraser Darling[16]. There are numerous examples where this has proved necessary in the interest of the species concerned as well as of other species, including man; deer and wapiti in North American national parks, red deer on the island of Rhum, hippopotami in the Queen Elizabeth National Park, elephants in the Murchison Falls and Tsavo National Parks. The effects of population pressure are somewhat different in large herbivores, such as these, from a predator such as the grey seal; but the implications are similar. If we protect a species from its normal hazards, in the case of grey seals by providing sanctuaries and an Act of Parliament, we must expect an increase in population. Indeed, this is the purpose of protection. The consequences may become severe in time, either to the species itself or to others, and in such cases a re-introduction of the hazards to survival may be desirable, especially if they can be kept under scientific control. Such a case is that of the grey seal in the north-east parts of Britain.

SECOND PARLIAMENTARY AND SCIENTIFIC CONFERENCE

By SIR WILLIS JACKSON, F.R.S.

Department of Electrical Engineering, Imperial College of Science and Technology, London, S.W.7

IN March 1961 a Parliamentary and Scientific Conference was held in London under the joint auspices of the Council of Europe and the Organization for Economic Co-operation and Development (O.E.C.D.), and afforded an opportunity for parliamentarians and scientists from several countries to discuss matters of common interest and concern. Since this Conference the subject of scientific policy has been receiving increasing attention, and no doubt its meaning and scope have become more clarified. An important contribution towards clarification was made by a report entitled "Science and the Policy of Governments" prepared in 1963 by an international committee set up by the Secretary-General of O.E.C.D., the publication of which was followed by a meeting of Ministers of the member countries of the Organization in Paris in October of that year. This meeting revealed a growing recognition that a scientific policy has become an essential component of national and international policy, but also the widely differing steps which the various countries have taken to cater for its formulation and implementation. An interim committee set up by the Ministers is now preparing material for a further meeting to be held probably during next year.

In varying degrees the scientist, technologist, economist, sociologist, employer, Trade Union official and parliamentarian all find themselves involved increasingly in the consideration of, if not in the taking of decisions on, such questions as the place which scientific research and technological development must occupy in national affairs, the resources which should be devoted to them, how these resources should be allocated and balanced in the light of overall national policy, and how to deal with their sociological consequences. The role of the parliamentarian in these matters is, or should be, a particularly important one. Yet all too few of them possess a sufficient knowledge and understanding of science to permit their effective participation in the discussion of many matters of major national and international importance. Correspondingly, however, many scientists are not good at communicating with the non-scientists, nor at appreciating the complexity of the issues, involving science, which fall to the parliamentarian for ultimate resolution.

The decision of the Council of Europe and of O.E.C.D. to organize a second Parliamentary and Scientific Conference, held in Vienna during May 23–27, was, therefore, a welcome one. Its objectives were stated to be to enable

Pergamon Press Publications

Tables of the Velocity of Sound in Sea Water

L.S.Bark, P.P.Ganson and N.A.Meister, U.S.S.R. Academy of Sciences, Moscow

Contents:
Foreword; Introduction; References; Part 1 – Tables of the velocity of sound t from —2° C to +33° C and S from 0 to 20%; Part II – Tables of the velocity of sound t from —2° C to +33° C and S from 20 to 40%; Inserts: 1 – Eight monograms for determining the velocity of sound; 2 – Table of the corrections Δv_p in m/sec at depths in metres.
Mathematical Tables Series – Volume 21
196 pages. 70s ($10.00)

Nonsteady Flame Propagation – AGARDograph 75

Edited by **G.H.Markstein,** Cornell Aeronautical Laboratory, Inc., Buffalo, N.Y.

Contents Include:
Steady one-dimensional flame fronts; General steady and nonsteady flames; Treatment of the flame front as a surface of discontinuity; Flow fields in the unburned and burned gases; Linearized treatment for small perturbations of flow field and flame shape; Boundary conditions at the flame front; Linearized equation of flame-front response; Dependence of burning velocity on flame shape and flow field; Phenomenological models; Explicit flame-response equations for various flame models; Two-dimensional propagating-wave disturbances.
334 pages. £5 10s ($16.00)

Single-Crystal Films

Edited by **M.H.Francombe,** Philco Scientific Laboratory, Pennsylvania, and **H.Sato,** Ford Scientific Laboratory, Michigan

Contents Include:
Theory of nucleation in deposition on substrates – J.P.Hirth, S.J.Hruska and G.M.Pound; nucleation of oriented films – T.N.Rhodin and D.Walton; Oriented growth in thin films of silver telluride – C.Paparoditis; Study of crystal growth in germanium films – T.O.Poehler and G.B.Gilbert, Jr; The observation of dislocations to accommodate the misfit between slightly different gold-palladium alloys – J.W.Matthews; Growth and imperfections in epitaxially grown silicon on variously oriented silicon substrates – S.Mendelson; Electrical conduction in thin epitaxially grown gold films – K.L.Chopra and L.C.Bobb.
432 pages. 100s ($14.50)

Progress in Boron Chemistry, Volume 1

Edited by **H.Steinberg** and **A.L.McCloskey,** U.S. Borax Research Corporation, Anaheim, California.

Contents:
The chemistry of compounds which contain boron-boron bonds – R.J.Brotherton; Some aspects of the coordination chemistry of boron – T.D.Coyle and F.G.A.Stone; The structures of the boron hydrides – G.W.Campbell, Jr; Nuclear magnetic resonance spectroscopy of boron compounds – R.Schaeffer; Boron compounds in cancer therapy – A.H.Soloway; Heteroaromatic boron compounds – M.J.S. Dewar; Organoperoxyboranes – A.G.Davies; Organoboron heterocycles – R.Köster; The reactions of diazoalkanes with boron compounds – C.E.H.Bawn and A.Ledwith; The chemistry of boronic and borinic acids – K.Torssell.
490 pages. £7 ($20.00)

Practical Handbook on Spectral Analysis

V.S.Burakov and **A.A.Yankovski**

Contents:
Introduction; Light sources for spectral analysis; Visual methods of spectral analysis; Photographic methods of spectral analysis; Procedures for the spectrographic quantitative analysis of metals and alloys; Methods of spectral analysis of powders and solutions; Setting up a spectral analysis laboratory.
208 pages. 80s ($12.00)

Gas Analysis by Gas Chromatography

P.G.Jeffery, Principal Scientific Officer, and **P.J.Kipping,** Senior Experimental Officer, Warren Spring Laboratory, D.S.I.R.

Contents:
Introduction; Sample transfer systems; Chromatographic separation; Detectors; Apparatus for gas analysis; Hydrogen; The noble gases; Some common gases; The hydrocarbon gases; Nitrogen compounds; Sulphur compounds; Halogen compounds; Miscellaneous compounds; Some complete analyses; Determination of gases in solid sample materials; Determination of gases in liquid sample materials; Gas sampling; References; Index.
International Series of Monographs on Analytical Chemistry, Volume 17
228 pages. 70s

Diamond Abrasives and Tools

Edited by **J.Burls,** Industrial Diamond Information Bureau

Contents:
Welcoming address – A.Todisco; Opening address – W.A.Chapple; Multipoint diamond dressers for form grinding – J.Cantrell; The application of diamonds in dressing tools – G.P.Freeman; Experiments with a new grinding technique – C.P.Hallez; The role of diamonds in profile grinding – N.R.Smith and N.J.Coombes; Factors influencing the economic use of diamond wheels for carbide grinding – L.J.Smith; A study of diamond as a unique abrasive material diversified in its grit types to suit different applications and carriers – J.deBourgues and R.N.Nunn; A new synthetic diamond grit and its application to heavier carbide grinding operations – H.B.Dyer and A.R.Roy.
128 pages. 50s ($7.50)

Digital Differential Analysers

A.V.Shileiko

Contents:
Introduction; Theoretical principles; Method of representing quantities in DDAs; Circuits for function-generator units; Principles of operation of digital differential analysers; Digital integration methods; Systems of numeration; Some special functions of digital integrators; Methods of using digital integrators to solve various problems; The accuracy of the DDA; The design of modern digital differential analysers; Serial DDAs; Parallel DDAs; The application of digital differential analysers; A survey of the problems solved; DDAs employed in automatic control systems; Conclusion; References; Index
116 pages. 45s ($6.50)

FLUORESCENCE

PHASE CONTRAST

TOGETHER! WITH THE NF MICROSCOPE FROM CARL ZEISS JENA

The new NF microscope is now equipped for :—★ Observations in Phase Contrast or Fluorescent Illumination—or both together. ★Absorption Photometry using a photo-multiplier. ★TV display using zoom projection. Plus standard attachments for :—1. Fully automatic or manual exposure control. 2. Bright Field and Dark Field Illumination. 3. Incident light observation. 4. Micro-hardness testing. 5. Studies in Polarised light. The NF also has a Pancratic condenser system and a complete range of Objectives and Eye-pieces.

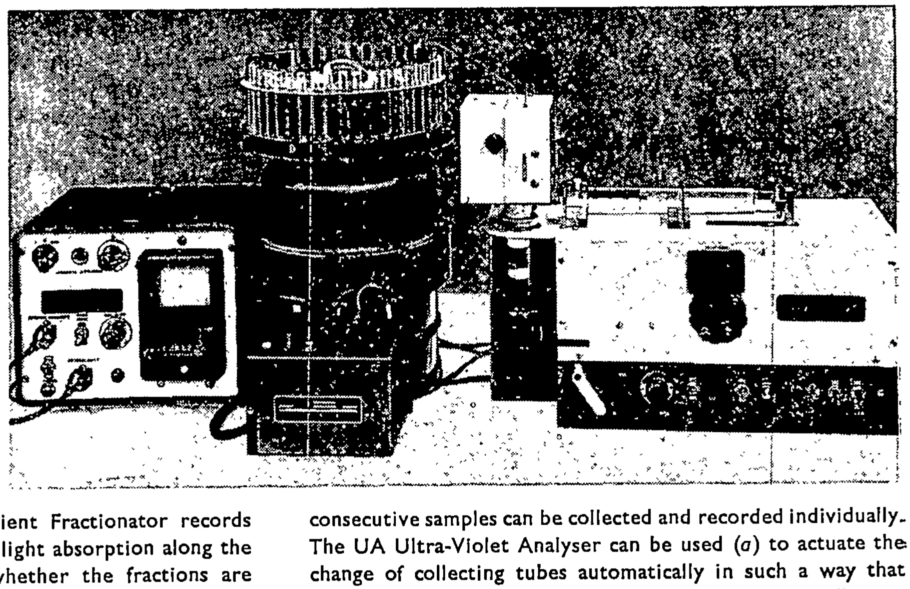
CARL ZEISS JENA

The ISCO Model D Density Gradient Fractionator

for sensitive quantitative measurement and recording of ultra-violet light-absorption at all depths in a gradient column after centrifugation



The ISCO Model D Density Gradient Fractionator records the complete profile of ultra-violet light absorption along the length of the gradient column, whether the fractions are collected or not.

If used with an auxiliary fraction collector (e.g., the ISCO Improved Model T) and Model UA Ultra-Violet Analyser, consecutive samples can be collected and recorded individually. The UA Ultra-Violet Analyser can be used (*a*) to actuate the change of collecting tubes automatically in such a way that each UV-absorbing zone is deposited in a separate collecting tube, and (*b*) to indicate on the chart the point at which the changeover is made.

Write or phone to-day for full details.

legislators to gain a better understanding of the problems, the needs and the perspective of science; to estimate better its effect on the national economy and on the development of the State; and to enable scientists to partake more fully in considerations which may give rise to political decisions.

The formal papers prepared for presentation at the Conference were a review of the aforementioned O.E.C.D. report and of the scientific situation in European countries and the United States by Mr. Kenneth Lindsay, a past Member of Parliament for the English Universities; and addresses by Prof. Gerhard Hess, President of the German Research Association; Mr. Quintin Hogg, Secretary of State for Education and Science in the United Kingdom; Mons. G. Palewski, French Minister of State for Scientific and Atomic and Space Research; and Mons. Karl Czernetz, Member of the Austrian Parliament.

Prof. Hess surveyed the history and philosophy of European science; the main theme of Mons. Palewski's address was that a national policy for scientific research had become essential to the independence of a country in the broadest sense, namely to retaining the possibility of a voice in world affairs and of expressing its own national genius; while the essence of Mons. Czernetz's contribution was concentrated in his statement that parliamentary democracy is in great danger if parliament is not asked to take part in the formulating of scientific policy, and where such policy is devised only by scientists and the government. The substance of Mr. Quintin Hogg's address follows.

It would be an over-statement to claim that the Conference made much progress towards its defined objectives, notwithstanding the many distinguished participants from twenty countries, due mainly to the generalized and diffuse character of much of the discussion, and to the way in which it alternated somewhat uncontrollably between the two themes, which Mr. Hogg tried at an intermediate stage to separate, of 'science for policy' and 'policy for science'. It is to be hoped that in similar future conferences an effort will be made to direct attention, and to sectionalize preliminary discussion, on a limited number of specific topics falling within these two aspects of scientific policy.

The communiqué which was approved at the conclusion of the Conference drew particular attention to the value of joint Parliamentary and Scientific Committees within individual countries; to the supplementary possibility of regular committees for scientific policy as part of parliamentary machinery; to the desirability of directing international co-operation in science to those areas in which international effort offers advantages as compared with national effort; and to the fact that the growth of scientific policy needs the support of an informed public opinion, involving much increased attention to scientific matters in the Press and other media of mass communication, and closer collaboration between journalists and scientists.

SPECIFIC PRESENT AND FORESEEABLE IMPACTS OF SCIENCE ON POLITICAL LIFE

By The Right Hon. QUINTIN HOGG, Q.C., M.P.

Lord President of the Council and Secretary of State for Education and Science

The impact of science on politics, and even the field of international affairs, has grown out of all recognition during the past seven years in which I have been responsible for the conduct of civil scientific research and development in the United Kingdom.

I propose to avoid, partly because it will be dealt with by others, and partly because I do not wish to traverse again ground which I myself covered last October, the specific questions of scientific organization and policy with which Parliaments and Ministers are increasingly concerned in their day-to-day life; not even the fascinating and increasingly important field of international, and specifically European, co-operation in the scientific field, exemplified among other things by the development of C.E.R.N., E.L.D.O., and E.S.R.O. in the field of space research, and *Dragon* in the field of applied nuclear science.

The Scientific Revolution

My task is to survey the specific present and foreseeable impact of science on society and political life. By 'science' I mean nothing less than thought systematically applied to the results of systematic measurement and observation. This is the specifically new factor in our modern civilization. Many ancient civilizations developed highly sophisticated and complex systems of thought which flowered as religions or philosophies. Some also indulged in a limited field in systematic observation and measurement with results which have left traces in modern astronomy and mathematics. But over a wider range and in the field of applied science, in the sense of the application of mechanical power to production and exchange, the achievements of the ancient world were, by modern standards, rudimentary. Genuine experimentation as distinct from the collection and classification of material was rare, and, so long as the individuals remained isolated, systematic enquiry in the modern sense (which is distinctively collective in character) was scarcely possible. The true scientific revolution began when scientists developed a corporate sense and when the era of collection and classification gave way over an extended field to data acquired by systematic experimentation.

My task, therefore, is to assess the impact of this revolutionary development in human thinking on society. Of the extent of this impact there can scarcely be any question. It is trite that we live in an era of change, rapid, cumulative, and accelerating. It is beyond question that these changes affect the size and viability of political organisms, the relations between classes and nations, the whole organization of society for production, the standards and distribution of education, property, wealth, hygiene and comfort, religious and moral beliefs, methods of waging war, the structure of the family, and the expectation of life. Moreover, it is beyond question, too, that the predisposing cause of all this change has been precisely the scientific revolution of which I speak. I would go so far as to claim that, in the wider sense in which I am accepting the subject set for me, the impact of science on society and political life is precisely the one question which, above all others, scientists and parliamentarians must set themselves to answer.

Expectation of Life

Perhaps the most fundamental change which science has brought about has been in the physical life and environment of the human species itself. I place these two factors above even the application of mechanical power to production, and communications. With the advent of surplus farming and modern hygiene in the nineteenth century, followed by the conquest of infectious disease and by modern surgery in the twentieth, the expectation of life has rocketed. Populations starting with those of the developed countries have exploded in size, an increase which shows every sign of intensifying as longer expectation of life extends, as it is already doing, to the less-developed parts of the world.

The productivity of agriculture and industry has in general kept pace with the rise in the expectation of life, but has not risen at such a pace as wholly to discredit the neo-Malthusians, who continue to predict food shortages on an immense scale by the end of the century and claim that the limits of agricultural productivity are visibly at hand. That this is a serious problem no one would doubt; indeed, it is something of a surprise to me both that it is so little discussed and that its effects are so little noticed. It is foreseeable, predictable and specific. Its impact on the society and politics of the latter half of the twentieth century may well be the major theme of the future political histories of our time. Nevertheless, I doubt the pessimistic views which are sometimes expressed —particularly in the West (but less in the East, since Marxism is traditionally anti-Malthusian)—as to the limits of possible increases in production. I would myself expect that we can immeasurably develop the food resources of Asia, Africa and South America. I suspect that we may soon be able to desalinate sea-water on a commercial scale and so irrigate the deserts. I would not put it beyond the bounds of possibility that we may discover means before long of actively cultivating the hitherto trawled but still unharvested sea.

I do not propose at this stage to raise the *ignis fatuus*, usually discussed *ad nauseam* on these occasions, of the perfect contraceptive as the complete answer to the problems of over-population in the developing countries. For aught I know this magic potion is just around the corner; on the other hand, its existence is not yet proved and even though it were found to exist its use in the conditions of Indian, African or Amer-Indian village life is problematical. What is certain to my mind is that the high birth-rate in the developing countries is less the product of the absence of such methods (since cruder methods of control have existed since the dawn of history) as of the simple desire for children in a society not yet used to low infant mortality rates and accustomed to regard a quiverful of offspring as a poor man's old age pension, a personal bodyguard or the answer to the servant problem. Social insurance, monogamy, later marriage, improved living and housing conditions, and a higher degree of personal security will, in my judgment, do more in the long term to lower the birth-rate than all the contraceptive pills in the world. These conditions will, I believe, follow on the development of agriculture and industry and an intelligent social policy.

Confrontation of Races

Perhaps the most spectacular and dramatic of the effects of modern science has been the confrontation between races, nations and classes. The scientists tell us that man has been on this planet for a few hundreds of thousands of years—even more if some interpretations of recent discoveries be accepted. By far the greatest part of this time we have spent our lives in isolated groups, removed from one another by countless generations of separation, behind insurmountable geographical barriers or untraversable distances, and such groups have remained for the most part innocent of elaborate political or social organization.

But modern communications make light of oceans, mountains, forests and deserts. Races, previously almost complete strangers, are now near neighbours. It is perhaps not surprising that in this new reunion of the human family, there have been heightened tensions and unedifying incidents. Modern methods of production have altered no less long-established relationships within communities, and as a result of developments in military science the nature of the relationships between established sovereign states is also in a state of near flux.

The process of confrontation will continue to occupy the front of the stage as the Earth becomes surrounded by an increasing number of orbiting satellites, continents conjoined by an ever larger number of radio networks and airlines, and individual countries laced by growing numbers of motorways. Served by large numbers of mechanically propelled vehicles, with towns sprawling ever wider, and expanding into vast densely populated conurbations utilizing ever-increasing quantities of water (the one natural product universally necessary for which there is no effective substitute), man is becoming more than ever a social creature and is becoming conscious more and more of a common destiny.

Environmental Problems

So much, for the moment, for the species. Now let us look at our physical environment. Not the least of our political problems arises from its increasingly artificial nature. This constantly presents new problems to the town planner, the traffic engineer and the social scientist. Complaints are made by all the developed countries of the depopulation of the countryside. But the centres of large towns are empyting, too. An American airline pilot is reported in a recent book as saying that as he flew across the American countryside now at night there were large black spaces which, not many years ago, were coloured with the lights of farms, but that the formerly discrete patches of light which showed the towns has broadened into great bands of lighted streets and suburban villas. This is happening in Britain, too. The population of the countryside is converging. But the population of the centre of cities is moving out. The population of Central London is less than it was fifty years ago in my boyhood. In the south-east of Great Britain great urban regions are developing into a regionalized subtopia. But the subtopia itself is not one of suburban villas and Manhattan skyscrapers. In the modern city high buildings are no longer allowed to form the artificial canyons of New York streets, but are spaced to reconcile the requirements of space and light with density. A new type of urban, or rather suburban, civilization based on the high building and the internal combustion engine is clearly on the way.

Our Natural Surroundings

Our natural environment is changing, too. Man has always, within the limitations of his technology, been more or less destructive of his natural surroundings. But his powers in this regard have changed in scale, and, therefore, in kind as well as in degree. Environmental problems are not confined to the growth of the cities and are not merely due to the lack of understanding of rural ecology shown by those nurtured in towns. New sporting —or unsporting—weapons, new methods of agriculture, and new industrial products present an increasing hazard to wild life and our natural biological environment. The large scale of modern scientific and military experiment also presents hazards to the wider physical surroundings in which we are placed. The rainbow bomb may have permanently altered the radiation belts in our immediate surroundings; bipole curtains outside the atmosphere could blanket out radiation from outer space. Military operations with nuclear weapons—or even renewed atmospheric tests if persisted in—would affect beyond human tolerance the actual physical environment in which we live. All these have a clear social and political implication calling for active effort on our part.

The Motor-car and Society

Scientific methods of transport and building stand among the major environmental influences at work. The automobile itself is a product of scientific achievement. Increasing ownership and use are a result of rising prosperity and increased leisure. Science has created a new problem here—how to obtain the benefits of the motor-car without losing the amenities of a modern urban society. To solve this problem we must use the resources of a whole range of scientific disciplines. Computer techniques enable us to analyse and apply vast quantities of information in the study of urban problems, and there is a role for mathematicians, statisticians and engineers in developing the use of new techniques. But, in the last resort, this is a human problem—there is vast scope for workers in the social sciences, as well as for planners and architects. This field is a good example of the need for bringing together the skills of many different disciplines to ensure that the benefits from scientific achievement are applied to the true advantage of society.

Construction Industries

A result of what has been happening has been an immense outburst of building and construction. But the ability of the construction industries in almost every country to carry the load required for the physical reconstruction of our urban and industrial environment is beyond its present means, man-power or methods. For the construction industry has been one of the last even to be industrialized, let alone automated. But this is clearly moving fast ahead. Modular construction, standardized and factory-built components, and new building materials are rapidly becoming standard practice, and new on-site methods and layouts are rapidly appearing. The architects' profession, once regarded as one of the fine arts, seems to be developing rapidly into a branch of civil engineering; the management and constructional design of buildings, once split up between the surveyor, the architect, and the builder, is rapidly becoming the task of an integrated team of professionals; while various methods of handling materials to and on the site are slowly taking the place of traditional habits.

Recreation and Leisure

One of the main results of the scientific revolution has been to bring adequate leisure and facilities for recreation within the reach of the masses. Catering for recreation and leisure is becoming a vast industry, but the emphasis is less exclusively on the traditional games. Sea, rivers, lakes, mountains, canals are becoming, and even further afield, the desert and the ice-cap may become, the playgrounds of the masses where formerly they provided the fields of exploration or of sports for the wealthy. Indoor entertainment and sport reach new elaboration and expense. It is also a mistake to think that the scientific age is contemptuous of the traditional arts and culture. Whatever we may think of popular standards of taste, enjoyment of literature, music and painting has never been more widely spread. The use of leisure in all its forms is part of the scientific and social revolution of our times. Yet the picture is not all bright. To win the constructive interest—and thus engage some of the leisure time—of the less talented and imaginative in worthwhile pursuits or social service is a common problem whether we are dealing with the 'stilyage' of the U.S.S.R., the hoodlums of New York or the mods and rockers of London's East End.

Energy Requirements

Cheap power is one of the main spearheads of the scientific revolution. The relative economics of nuclear and fossil fuels appear to vary from year to year, but it is still expected that nuclear stations will, at base load, provide the most economical means of generating electricity by the 1970's. By the end of the century we can surely expect that nuclear generation will be far cheaper than any of the older methods and that means will be found of consuming the plutonium which is a by-product of uranium-fuelled stations. Soon after it is possible that nuclear fusion processes will be contributing to energy supplies. But it is also, I would have said, certain that other new methods of generation, the fuel cell and perhaps heat convectors using cæsium vapour, will have been developed.

Advent of Automation

I now turn from the broad prospect of man and his environment to the more specific issue of methods of industrial production. We are already beginning to enter the age of automation and to feel the political and social effects of control engineering. As the century progresses this series of technological changes will produce important social and political consequences. The industrial methods of production of the nineteenth century created the urban working class, the miner, the factory worker, the railwayman, the clerk in the city office. It is possible that the control engineering of the twentieth century may end by destroying this class and substituting others more highly trained, better educated, with different economic functions. The computer and automatic processes of production, inspection, packaging and despatch will take the place of much unskilled labour. The demand is for new skills with different applications. I have some doubt whether this change need cause the structural unemployment which is said to have occurred in the United States. I cannot help feeling that a little more foresight in diversifying industry, a more careful phasing of redundancies and perhaps a more vigorous attitude to re-training, might at least have been worth trying. In the long run, however, the age of automation will produce its own demand for labour. Maintenance and other services can absorb the skill and labours of a population whose rising wages and improving educational standards and higher degrees of discrimination constantly increase levels of effective demand.

New Skills

The advent of automation, however, brings new problems to management, labour and educationists. While the nineteenth century created a network of highly specialized craft skills superimposed on an unskilled proletariat, and the early twentieth brought into being a huge army of semi-skilled factory operatives, the automative age calls for skills of a higher, more flexible, and less-specialized type. Where automation brings unemployment, it strikes the under-educated and unskilled earlier and several times more severely than the skilled. This means that the age of automation demands a higher general level of education and can do with far fewer specialized craftsmen trained by the traditional methods of apprenticeship to a single trade. It also throws up a special problem of adult training and re-training in fresh skills or in a higher degree of accuracy and perfection in old skills.

Management

It is, however, in the field of management and of decision-making that automation may effect the greatest social change. It is not simply that the computer eliminates the black-coated clerk from the processes of record keeping and calculation. It is that much that previously depended on hunch and flair in the realm of decision-making has proved to be capable of precise calculation by feeding a sufficient number of carefully programmed variables into an 'electronic brain'. This does not, of course, mean that there is less scope for scientific management, but far more. With such a flexible and sophisticated tool at his command, the modern business manager needs greater understanding exactly in proportion as he can pursue his predictions into ever greater accuracy.

Transport

It is quite certain that new methods of transportation will link countries even more together and lead to even more intimate economic interdependence. Not merely water, oil, and gas, but solids, possibly encapsulated, or in suspension, will be transported by pipeline. It is probable, though not certain, that new methods of land transport will have evolved. No one knows at present the future of the monorail, the hovercraft, or the hydrofoil. Ships will have automated engine rooms, and will probably be designed for automatic loading and unloading at the port. It is uncertain whether they will be served by nuclear reactors. Aircraft will be supersonic with perhaps vertical take-off and landing and fully automatic landing for passenger aircraft. Radio and telephone communications will almost certainly be increasingly by satellite.

Agriculture

The movement towards subtopianism already indicated will be intensified by modern agricultural methods. The agricultural industries of Europe will continue to produce more food with fewer employees. This process continues in Britain, but in Germany and France it will have even more drastic effects. Fertilizers, pesticides, and intensive methods will continue to boost output. It is probable that new pesticides will continue to create ecological problems needing prohibition and control. It may also be that the introduction of biological controls and more selective chemical pesticides will diminish the hazards which at present exist.

The primitive methods of agriculture in other parts of the world will gradually become mechanized. As the chemical industries contribute increasingly to the production of new materials, more land should become available for food production. One hopes that tobacco culture will gradually become a thing of the past.

The food-producing industry will make further advances in freeze-drying, packing and processing. It is possible that irradiation techniques will be widely used to prevent or delay spoilage from bacteria.

Medicine

Recent medical advances will clearly accentuate the problems attendant on old age. The doctors can prevent us dying, but there is no sign yet that they have learned how to keep us young. Further virus diseases may well be conquered by vaccines or new chemical inoculations. A surgery may possibly be developed to overcome the difficulty of engrafting spare organs and for utilizing electronically controlled artificial limbs. With the increasing numbers in society who will live on to a green old age, it seems that medicine will concern itself increasingly with the conditions and diseases attendant on old age and with mental health. Meanwhile social and preventive medicine, sanitation and human genetics are already coming to the fore as fields of study.

In the hospital world, the impact of new scientific advances, and especially of automation, is requiring much consideration in the context of the designing of new and improved hospital facilities. Equipment is becoming even more complex and varied and this has its impact on the staffing of our hospitals.

Education

The varying effects of the strange changes through which we have passed have already brought the question of the education of the young very much to the fore. A generation ago it would have been almost unthinkable even for a society modern by the standards of that time to afford a secondary education for all and a university education for all who can make use of it and desire to do so. This, and nothing less, is the proclaimed object and almost the accomplished achievement, of a number of European States, Great Britain among them. In the meantime the growing *tempo* of technical change makes the refresher course for adults in the more technical professions, medicine, management, engineering, teaching, and soon, perhaps even law, virtually a necessity, while the proportion of students going on to do postgraduate work and research, or attending schools of advanced study, is steadily increasing. If the age of automation makes this economically possible, it is also a technical requirement of the age of automation, and probably a condition of its success. So far from being the century of the common man, the twentieth may well become the age in which the qualified man holds the reins of political and economic power and adequate specialized qualifications may become within the reach of all. The uneducated tycoon of plutocracy, and the anonymous mass of the uneducated, may well be on the way out.

The 'Sixty-four Thousand Dollar' Question

Having said all this, I am conscious of having said almost nothing at all in the sense of answering the questions we all ask and to which we must all find answers if we are to survive. Most of the conditions of our future existence are all discernible in the present, and, though there may, and almost certainly will, be new scientific discoveries which are not discernible in present trends, I know of no method short of the necromancer's crystal ball to enable me to predict them.

The real issues, however, are altogether different. What has all this to say about peace or war, about life and death, freedom or enslavement, the abolition of poverty, the possibility of civilized amenities for the vast under-developed areas in Asia, Africa and South America, the relationship between 'East' and 'West', or the organization of our society?

These are not questions to which science as such can provide an answer. Yet it is precisely the development of the scientific revolution which I have been attempting to describe which presses the necessity for an answer upon us.

I do not think that politics is likely to become a purely scientific occupation. Let anyone who thinks the contrary consider the number of parameters to be identified and the extent to which human purposes are incapable of being settled by agreement. Yet can we be satisfied with a negative answer? In one specific direction the politician must become a scientist—a social scientist—or he will become a demagogue and a charlatan.

It is a commonplace, which nevertheless has some truth in it, that society has not grown up as fast as technology. We have not yet learnt how to live on tolerable terms with many of the new tools it has put in our hands. For Governments this situation presents the particular difficulty that, alongside all the quasi-certainties which the physical sciences present to them, there is a large area of uncertainty and ignorance about human nature and human behaviour, both individual and in society. It is largely this uncertainty which makes political decisions so hazardous and difficult. A Minister must work with, through and for the benefit of human beings. I think this means at least that far greater attention should be directed to the social sciences, and the necessity of Parliamentarians knowing something about them and the arts of decision-making as well as of the traditional humanities and physical sciences.

My visit to the U.S.S.R. last summer convinced me that, contrary to the official doctrine of both sides, the effect of technical and scientific change will be to drive the economic and social systems of developed nations more closely together. The environmental problems of developed industrial society are driving the free-enterprise nations into heavier and heavier investments of social capital despite their continued emphasis on private-consumer choice. The rising standards within the U.S.S.R. are driving the Soviet Government to produce a wider range of consumer goods in the shops. It is doubtful how far the former can be indefinitely accommodated within the previously accepted assumptions of capitalist society. But I also feel certain that a wide range of consumer choice available to the individual is quite inconsistent with the hitherto accepted norms of socialist planning. Indeed, it is not without significance that the Soviet doctrine is that Communism, that is, the phase at which Socialism with the State itself according to orthodox Marxism withers away, is coming within the next twenty years. Should it come, I fancy that it may not turn out to be so different from the American way of life as the inhabitants of the Kremlin or the White House might expect.

Moreover, under the impact of increasing wealth, the level of education is rising everywhere. On the whole this must favour freedom of speculation in the East and in the West. University graduates, whether in the sciences or the arts, are kittle cattle. But at least it is difficult to keep them to a rigid orthodoxy of any kind, or to prevent them from asking themselves, or one another, the questions, perhaps insoluble, which have haunted the human race wherever their standard of living has risen above the level of poverty. A scientific friend of mine was being shown round a scientific institute library by his Soviet host, when they passed the political section filled with the orthodox literature of Marxism–Leninism. "This is our theological section," said the Russian to my friend, and while the remark undoubtedly illustrates the absence in both of orthodox religious belief it is a scarcely less-convincing argument for the lack of any real conviction about the official political theory. A Soviet scientist visiting Britain was asked in a university common room what changes he had seen in Britain since he was last in this country more than thirty years ago. His astonishing reply was that Britain had travelled further on the road to Socialism than the Soviet Union. I do not profess to understand, far less agree, with this judgment; but at least it goes to show that the preconceived categories of opinion among the Soviet intelligentsia are less rigid than might be supposed.

With the capitalist and the socialist worlds converging towards each other from opposite directions and each competing for the favours of the politically developing but economically undeveloped nations, what in the end can we foresee as the impact of the scientific revolution for mankind?

Need for a Common Culture

We see, I believe, the urgent need for a common culture, a generally accepted standard of social and political values, a commonly enforced and recognized ethical and political code between men, between nations, between races, between classes. We see also the necessity for an international mechanism more effective than that provided simply by diplomatic contacts, functional organizations, military alliances, or even the United Nations.

I am well aware of the dangers of advocating, in any era of ideological struggle, anything which even savours of the co-existence of ideas as distinct from the co-existence of people. But if we are to co-exist as people, and if our mutually incompatible ideas are to lock in the dialectic of history, it is above all things necessary that races, classes and states—yes, and individuals—should work out, understand, and observe some objective rules of behaviour mutually acceptable and universally understood if only for the conduct of the struggle. For this purpose there must be communication, there must be established dialogue, and those who seek to explore, each with loyalty to his own people, the minds of the other side must not be condemned as revisionists or fellow travellers. The logic of history demands that human beings, as well as being the masters of their environment, should also learn to control and mitigate the violence of the very forces which make for conflict. I myself was proud last summer to play, with others, a part in the negotiation of the limited test ban agreement later signed in Moscow. It caused me real pain to see some of those who had taken part with me in the negotiation, which seemed to me a logical political corollary of the scientific revolution, condemned by doctrinaire and sectarian extremists of their own camp as traitors to their own side.

To my mind, the necessary corollary of the scientific revolution, the urgent necessity of our time, is to break down cultural, political and racial barriers and especially to break down the barriers between East and West, between the developed and the developing, and all the other remaining psychological barriers which, after all, are the relics of an age when we could afford to ignore races and nations who were not our immediate neighbours, and could afford without ultimate disaster to go to war with those who were. These days the scientific revolution has brought to an end. I do not mean that, in the world of the future, differences of language, culture, personality, colour should cease to exist. Freedom under the law does not extinguish—perhaps it even enhances—a variety of individual and national expressions. That at least has been our experience of it in Europe, where we have been, for upwards of four thousand years, at once the guardians and the heirs of the slowly evolving and dynamic tradition of freedom under the law, self-disciplined freedom under a law carrying moral as well as positive authority. But the need for such a system of law and morality acceptable to the different races and creeds of the re-united human family is perhaps the most specific question which the scientific revolution compels us to face. Unless we face it, not all the increased control of our physical environment will save us from disaster. If we do, there is, perhaps, ahead of us an age of magnificence and splendour equalling the rosiest dream of poets, prophets and philosophers.

OBITUARIES

Prof. Ø. Winge, For.Mem.R.S.

Prof. Øjvind Winge, director of the Physiological Department of the Carlsberg Laboratory, Copenhagen, died on April 5, after a long illness at the age of seventy-seven.

Some years ago, at a ceremony in memory of the founder of the Carlsberg Laboratory, the brewer J. C. Jacobsen, Prof. Aksel Tovborg Jensen expressed that he felt he had a right to say that the men of the Carlsberg Laboratory have always administered the founder's rich endowments well ; and he continued: "Emil Chr. Hansen's and Joh. Kjeldahl's successors – Johs. Schmidt, S. P. L. Sørensen, Kaj Linderstrøm-Lang and Øjvind Winge – stand as leading lights of their sciences in Denmark and in the wide world as the equals of the greatest. They have done credit to their country and to J. C. Jacobsen, Denmark's great son."

A finer monument can scarcely be imagined, and with this as a background we shall remember Prof. Winge's achievements in genetics and brewing science.

Øjvind Winge was born in Århus in 1886; he started his career as an assistant to Prof. Johs. Schmidt at the Carlsberg Laboratory, and in 1921 he was appointed professor in genetics in the Royal Veterinary and Agricultural High School in Copenhagen. During this period he wrote a most outstanding text-book on genetics.

After the death of Johs. Schmidt in 1933, Øjvind Winge succeeded him as director of the Physiological Department of the Carlsberg Laboratory. He immediately took up research on yeast and here introduced the breeding of new hybrids by crossing and by the combination method, and contributed largely to our knowledge of the sex-life of yeast, its meiosis and its fertilization mechanism. The micromanipulation technique, elaborated by Winge and Laustsen as a necessary new microscope technique, is now commonly used in heredity investigations and yeast breeding.

Theoretical investigations of yeast first of all comprise the heredity conditions of the fermentation enzymes, and they have contributed to a knowledge of the nature of the gene and its mode of operation. Inheritance of the morphological properties has also been thoroughly investigated, and of heterosis, even to a pronounced degree, in certain crossing combinations of yeast, has been demonstrated.

Degeneration phenomena of normal brewer's bottom yeast, poor formation of spores, and low fertility in the spores have resulted in the fact that the combination breeding could not be utilized in the brewing industry. With the production of baker's yeast, on the other hand, both breeding and heterosis effect have been utilized.

In the science of brewing, Prof. Winge will be specially remembered from his breeding work with barley and hops. The plant-growing part of the work was carried out at 'Nordgården', the experimental farm belonging to the Carlsberg Breweries, where Prof. Winge was the scientific leader during 1938–62. With regard to barley, the variety Carlsberg II, on the market in 1953, attained a wide distribution as a high-yielding and acknowledged malting barley. Its outstanding qualities have left their marks on the European barley-breeding, often being used as crossing material in many European countries.

Winge's work on breeding of hops is especially familiar to specialists, but here it is highly esteemed. We are grateful to Prof. Winge for his review last year in *Comptes Rendus des travaux du Laboratoire Carlsberg* of his experiences: "Fifty Years of Hop Breeding at the Carlsberg Laboratory and Nordgården".

Prof. Winge received many scientific honours, among those many honorary doctorates, and he was elected a member of numerous scientific academies all over the world. For several years he was chairman of the group of natural scientists in the Royal Danish Academy of Science and Letters. He was an inspiring teacher, and his researches have been in front ranks both in connexion with yeast and with barley and hop breeding.

BIRGER TROLLE

Prof. R. McKay

ROBERT MCKAY, who died on May 4 at the age of seventy-five, was emeritus professor of plant pathology in University College, Dublin. Born in County Antrim, he received his early education there. He entered the Royal College of Science for Ireland in 1912, but his studies were interrupted from 1915 until 1919, during which time he served with the Royal Army Medical Corps in France. In 1920 he became an Associate of the Royal College of Science, and after a short period of service with the Seed Propagation Division of the Department of Agriculture, he joined the Plant Disease Division as Assistant to the late Prof. Paul A. Murphy. Following the death of Prof. Murphy in 1938, McKay became head of the Plant Pathology Department, which had been transferred to University College, Dublin, in 1926. In 1940 he was appointed to the post of lecturer and in the same year was awarded a D.Sc. degree of the National University of Ireland. He was appointed professor of plant pathology in 1945.

Prof. McKay's earliest work, in collaboration with Prof. Murphy, was concerned mainly with investigations on potato virus diseases. The technique worked out by these investigators of testing nucleus stocks of potatoes in the glasshouse and propagating such stocks under conditions of good isolation and rigid inspection has been largely responsible for the high repute in which Irish seed potatoes are held.

Onion mildew was probably the first of the fungal diseases worked on by Prof. McKay. With Prof. Murphy, he demonstrated the presence of hibernating mycelium in bulbs from diseased plants and that such mycelium could be killed by heat treatment. This is one of the first references to control of a fungus disease by heat treatment. Prof. McKay was the first to observe the germination of the oospores of the onion mildew fungus, and he showed that such spores could remain viable in the soil for up to twenty years. His work on diseases of cereals, particularly on *Septoria* leaf spot of barley, *Helminthosporium* leaf spot of oats and diseases of wheat caused by *Gibberella* has added much to our knowledge concerning these maladies. During the Second World War, flax growing was an important industry in Ireland, and Prof. McKay made a study of the diseases occurring on that crop. With his co-workers, he was the first to demonstrate clearly that the fungus causing the pasmo disease of flax was seed-borne. He carried out spraying trials on the control of apple scab over many years and he pointed out the importance of bud scale infection as a source of the apple scab fungus under Irish conditions. He studied beet diseases, and it was mainly due to his advice to the Irish Sugar Company that the practice of growing stecklings and sugar-beet crops in isolation was adopted many years ago. This practice has resulted in considerable reduction in such diseases as virus yellows and downy mildew in these crops. Among other diseases which he investigated were blight and scab of potatoes.

As adviser in plant pathology to the Department of Agriculture, he came in contact with most of the diseases occurring on commercial crops in Ireland. The knowledge thus gained he committed to writing in a series of monographs on diseases of individual crops. These monographs, so well and so profusely illustrated, are of immense value to growers, advisers and students of plant pathology.

His monographs on diseases were subsidized by the Irish Sugar Co. (sugar beet diseases), the Irish Potato Marketing Co. (potato diseases), Messrs. Guinness (cereal diseases), and the Flax Development Board (flax diseases). He was honoured by the Royal Horticultural Society of Ireland by the award of the Medal of Honour in 1948 and by the Royal Dublin Society by the award of the Boyle Medal in 1957.

Prof. McKay's work covered a wide field of research, but it was always carried out with thoroughness and perseverance. Whether fundamental or applied, all of it is sound and reliable.

As a teacher, Prof. McKay is remembered with affection and respect by hundreds of graduates in agriculture. As a lecturer he was painstaking in keeping up to date with his subject and in delivery he was clear and lucid. His lectures were often interspersed with witticisms, for he had a lively sense of humour. Under the auspices of the Royal Dublin Society he lectured on plant diseases to growers in almost every county in Ireland. His practical approach to the subject, and his awareness of their needs, earned him the appreciation of growers throughout the country.

J. B. LOUGHNANE

Miss E. H. Ekins, O.B.E.

MISS E. H. EKINS died at Hitchin, Hertfordshire, on June 4. She was eighty-four.

Emily Helen Ekins, daughter of A. E. Ekins, public health analyst for Hertfordshire, was educated at St. Albans High School, the University of Birmingham and Studley College, Warwickshire. She joined the staff of Studley College as a lecturer in horticulture in 1911, became acting warden in 1922 and principal in 1924, which position she held until August 1946. She was awarded the O.B.E. in recognition of her services to agricultural education in 1934.

Miss Ekins will long be remembered as one of the pioneers of agricultural and horticultural education for women. During the twenty-two years she held office as principal of Studley College she put her whole-hearted energy into consolidation of the administrative and educational sides. Building developments began in 1925; two appeals were launched, one to purchase the freehold of the property from the Warwick Estate and the second for the building of science laboratories and study bedrooms, and despite difficulties and frustrations, all-round progress in the history of the College was evident, brought about by her integrity and single-mindedness. She will also be remembered by hundreds of students who recognize and appreciate the vast amount of service which she so generously gave; she was the chief link in binding together each generation of students throughout her long association with the College, and many of them will remember with gratitude the help and encouragement she gave during their training and early days of their career.

NEWS and VIEWS

International Meteorological Organization Prize for 1964: Dr. F. W. Reichelderfer

Dr. F. W. Reichelderfer, formerly chief of the National Meteorological Service, U.S. Weather Bureau, has been awarded the International Meteorological Organization Prize for outstanding work in meteorology and international collaboration.

Dr. Reichelderfer was born on August 6, 1895, in Harlan, Indiana. He obtained a B.A. at the Northwestern University and joined the U.S. Naval Reserve Flying Corps in May 1918. After meteorological studies at the Harvard Meteorological Observatory he was appointed chief of Naval Aerological Service from 1922 and continued in that capacity until 1928. From 1928 until 1938 he served on U.S.S s *Oklahoma* and *Lexington*, and as executive officer on board U.S.S. *Utah* and in the naval air station at Lakehurst, New Jersey, for lighter-than-air craft. In this latter capacity he participated in a flight of the German zeppelin *Hindenburg* from Lakehurst to Rio de Janeiro and Frankfurt and back in 1936. He was appointed chief, United States Weather Bureau, in 1938, and retired from office in 1963. Dr. Reichelderfer actively participated in international meteorological work both in the International Meteorological Organization (1938–51) and the World Meteorological Organization (1951–64). He participated in preparing the International Convention adopted in Washington in 1947 which created the World Meteorological Organization. He served as the first president of the World Meteorological Organization, after the Convention entered into force, from 1951 until 1955. He was a member of the Organization's Executive Committee from 1951 until his retirement in 1963. He also participated in the international scientific activities in meteorology undertaken by the International Union of Geodesy and Geophysics. Dr. Reichelderfer is still active in a large number of scientific bodies in the United States, such as the National Academy of Sciences, the American Association for the Advancement of Science, the Institute of Aeronautical Sciences, the American Geophysical Union, the American Meteorological Society, over which he presided during 1945–46, and was a member of the National Advisory Committee for Aeronautics for many years.

Physical Chemistry in the University of Exeter: Prof. M. L. McGlashan

Dr. M. L. McGlashan, reader in chemistry in the University of Reading, has been appointed to the newly established chair of physical chemistry in the University of Exeter as from October 1. Dr. McGlashan was born in New Zealand. He graduated with a first in chemistry from the University College (now University) of Canterbury, Christchurch, and joined the teaching staff there. In 1949 he entered the University of Reading with the first Sims Empire Scholarship and obtained a Ph.D. degree for his work on theoretical chemistry, which he carried out with Prof. E. A. Guggenheim. He returned to Christchurch and was made senior lecturer; but in 1954 he joined the staff of the University of Reading. At Reading, Dr. McGlashan has won a reputation for his theoretical and experimental research in the field of intermolecular forces. He collaborated with Prof. Guggenheim on a variety of problems in statistical mechanics, and he built up an important research group making measurements of the thermodynamic properties of liquid mixtures and of gases. He was awarded a D.Sc. degree of the University of Reading in 1962 and in that year was given the title of reader. He is an enthusiastic mountaineer and is keenly interested in the theatre. His three Shakespearean productions for the University Drama Society are well remembered.

Department of Pure and Applied Chemistry: University of Strathclyde

The granting of a charter to the University of Strathclyde, formerly the Royal College of Science and Technology, Glasgow (*Nature*, 199, 1137; 1963), has approximately coincided with the completion of a new building to accommodate the University's chemical activities. The opportunity has been taken to reorganize these activities within a new framework by the formation of a Department of Pure and Applied Chemistry from the former separate Departments of Chemistry and of Chemical Technology. The new Department will be headed by a committee of professors, initially consisting of Profs. P. D. Ritchie (chemical technology), P. L. Pauson (organic chemistry) and M. Gordon (physical chemistry). Prof. Ritchie will be chairman of this committee for the academic year 1964–65. The Organic Chemistry, Physical Chemistry and Chemical Technology Sections of the Department have now moved into the new building on Cathedral Street, which provides greatly increased facilities for both teaching and research. Part of the old George Street building is being retained for the Inorganic Chemistry Section, and for the use of first-year classes. The staff has been augmented by the appointment to lectureships of Drs. S. R. Logan (physical chemistry), A. McAuley and G. A. Melson (inorganic chemistry). Dr. D. Pugh has been appointed to an assistant lectureship in theoretical chemistry, and Dr. W. E. Watts to a temporary lectureship in organic chemistry; and Dr. S. Affrossman has been promoted from assistant lecturer to lecturer in physical chemistry.

The Morecambe Bay Barrage

In reply to a question in the House of Commons on June 11, the Parliamentary Secretary to the Board of Trade, Mr. D. Price, said that Mr. E. Heath had asked the North-West Study Group to make a thorough assessment of the material already available about the proposals for a Morecambe Bay barrage. Under the scheme, a road and rail link would be incorporated enclosing the estuaries of the Leven and Kent and the waters would be used for public supply and for cooling locally sited power stations. The assessment was to be made in order that the Minister might determine whether a survey was needed and, if so, on what lines it should be undertaken. He would willingly receive any further information on the proposals, and proposals for such projects as a barrage and road links across the Solway Firth would also be readily received by the Study Group. The Ministry conceived it as part of the Group's duties to take these into its general reviews.

Aid to Developing Countries

In reply to a question in the House of Lords on June 18, the Chancellor of the Duchy of Lancaster, Viscount Blakenham, said that aid to developing countries from British public funds in 1963 was £158 million, compared with £150 million in 1962. For the financial year 1963–64, expenditure was £175 million compared with £148 million in 1962–63 and £160 million in 1961–62. These figures did not include the substantial flow of private investment, nor the £24 million of military aid provided in 1963 or the £30 million of military aid made available in 1963–64.

The Minister of State for Commonwealth Relations and for the Colonies, the Marquess of Lansdowne, said that, according to a joint statement issued by the British and Southern Rhodesian Governments on June 4, the latter Government had now agreed to assume responsibility for maintaining and developing the University of Rhodesia and Nyasaland as an independent institution open to all races. The British Government agreed to contribute £750,000 towards recurrent expenses up to 1967; a capital grant of £800,000 for building the teaching hospital; and some £300,000 towards general capital expenditure.

Commonwealth Bursaries Scheme

THE tenth annual report of the Royal Society and Nuffield Foundation Commonwealth Bursaries Scheme covers the year ended December 31, 1963, in which 24 bursaries were awarded, five for visits from the United Kingdom (two to Australia and one each to Canada, the Falkland Islands and Uganda), 15 for visits to the United Kingdom (four from Australia, five from India, and one each from Canada, Jamaica, New Zealand, Nigeria, Sierra Leone and Singapore), and four for visits between countries of the Commonwealth other than the United Kingdom (Pp. 8. London: The Royal Society and the Nuffield Foundation, 1964). Of the 56 applications considered, 43 were for visits to and 8 for visits from the United Kingdom. During 1963, besides the £5,000 from the Nuffield Foundation and the Parliamentary grant-in-aid to the Royal Society of £4,000, funds available included £1,200 from Canada, £796 16*s*. 3*d*. from Australia, £561 10*s*. 5*d*. from Pakistan, £500 from India, £400 from New Zealand, £150 from Sierra Leone and £100 from Ceylon.

Southern Hemisphere Telescope

FOUR British astronomers, led by the Astronomer Royal, Sir Richard Woolley, have just left for Australia for exploratory discussions with Australian astronomers of a proposal to build a 150-in. optical telescope there. These discussions may then enable the Royal Society and the Australian Academy of Science to put proposals to the United Kingdom and Australian Governments for the support of a full design examination for the telescope. At present there are 74-in. telescopes at the Radcliffe Observatory, Pretoria, South Africa, and at Mount Stromlo, Australia, but a larger telescope would improve ability to explore the southern sky. Such a telescope could examine such interesting objects as the Magellanic clouds and the centre of the Milky Way, which is not easily observed by existing telescopes in the Northern Hemisphere. It would also supplement the superb facilities for radio-astronomy already established in Australia. Funds for this exploratory visit are being provided by the Department of Scientific and Industrial Research. The other members of the party are: Prof. R. O. Redman (University of Cambridge) and Dr. A. Hunter and Mr. J. D. Pope, both of the Royal Greenwich Observatory.

Expenditure on Research and Development in France

ESTIMATES of French expenditure on research and development given in a pamphlet issued by the French Embassy, Service of Press and Information, indicate that the French Government expended some 4,000 million francs on research and development in 1962, or about 4 per cent of the budget (*France's Expenditure on Research and Development*. Pp. 17. London: Ambassade de France, Service de Presse et d'Information, 1964). Of this expenditure, 1,973 million francs went on civil and military atomic research and investigations and 1,519 million francs on military research, designing and prototypes. Of the total, 1,327 million francs were distributed through the Minister of State for Scientific Research and Atomic and Space Questions and 784 million francs through the Ministry of Education. Research expenditure by business firms in 1962 amounted to 2,300 million francs, or some 3·5 per cent of the turnover. This represented an increase of about 24 per cent on the previous year, and of it 40 per cent was in the engineering sciences (excluding electronics and electro-techniques), 28 per cent in electronics and electro-techniques, 15 per cent in chemistry and 10 per cent in physics other than electronics. Two-thirds of the industrial expenditure on research was borne by some fifty firms.

Railway Services in France

A FURTHER note issued by the Press and Information Service of the French Embassy describes the Société Nationale des Chemins de Fer and the French Railways, including its general organization, the magnitude of the traffic and the changes made since the Society was established in 1938 (Pp. 16. London: Ambassade de France, Service de Presse et d'Information, 1964). While the staff was reduced from 515,000 in 1938 to 348,500 in 1962, the productivity of staff increased by 160 per cent, the productivity of engine units by 360 per cent and that of passenger-carrying vehicles by 240 per cent, together with a relative drop of some 70 per cent in the consumption of energy compared with that prior to the Second World War. There are now 7,780 km of electrified track compared with 3,340 in 1938, and some 1,100 Diesel rail car units are in operation together with about 900 slip coaches, providing about 40 per cent of passenger train runs.

Society for Developmental Biology

THE inaugural meeting of the new Society for Developmental Biology was held on June 20 in Oxford. The programme consisted of scientific papers given by biochemists, botanists and zoologists. Dr. J. Gurdon (Department of Zoology, Oxford) discussed the significance of differences in the ribosomal RNA of haploid and diploid embryos of *Xenopus laevis* and described some changes resulting from nuclear transfer experiments. Prof. C. W. Wardlaw (Department of Botany, Manchester) then gave a general review of recent work on plant embryos, and Dr. E. Huehns (Department of Biochemistry, University College, London) concluded the morning session with a summary of his work on the structure of human embryonic hæmoglobins. In the afternoon, Dr. P. Burch (Department of Medical Physics, Leeds), in a paper entitled "The Molecular Basis of Self-recognition and Mitotic Control", speculated that the same genes may encode for both these types of control mechanism. His ideas provoked some discussion, which was continued after Prof. W. S. Bullough (Department of Zoology, Birkbeck College, London) had described the effects of adrenaline on mammalian epidermis, where a constant cell population appears to be maintained by parallel changes in mitotic rate and rate of cell death. The next two papers, given by Dr. K. R. Ashby (Department of Zoology, Durham) and Dr. J. M. Ioannou (Department of Anatomy, Birmingham), were concerned with the development of gonads and germ cells. Dr. R. M. Gaze (Department of Physiology, Edinburgh) discussed the development of neuronal connexions after combinations of two temporal or two nasal halves of the eye in *Xenopus laevis*. After tea, Dr. P. R. Bell (Department of Botany, University College, London) described histochemical and autoradiographic investigations of the distribution of DNA in fern eggs, then Dr. Webster (Department of Zoology, King's College, London) discussed enzyme activities in normal and regenerating *Hydra*. At a business meeting immediately after the scientific proceedings, the Society's constitution was adopted and its officers and committee elected, and it was planned to arrange two or three meetings each year in the future.

British Food Manufacturing Industries Research Association

THE annual report for 1963 of the British Food Manufacturing Industries Research Association has recently been published (Pp. 68. Leatherhead: The British Food Manufacturing Industries Research Association, 1964).

The topics in the research programme covered work on a wide range of materials, including cocoa and chocolate, sugar confectionery, bakers' prepared materials, jam, pickles and sauces, meat and fish products, oils and fats. During the year, the Association published and distributed to members six research reports, two scientific and technical surveys, one review of research and twenty-eight technical circulars. Members of the staff also contributed to fourteen other scientific and technical publications during the year. Both the Analytical and the Bacteriological Services report an increased number of samples examined for Association members. The Information and Library Services report that the number of abstracts published during 1963 rose to 2,306 (1,844 in 1962) and their value to members is shown by the fact that the Association received requests for a sight of the original article for one-third of this number (excluding patents). The Director reports that the Association is now prepared to accept 'sponsored' work, provided that the results are likely to be of interest to a substantial number of members. Special projects already in progress at the beginning of 1963 included two "Public Law 480" contracts for the U.S. Department of Agriculture on the biochemistry of bacon curing and the glyceride composition of cottonseed oil. This should assist the Association in many ways, not least in aiding in the procurement of some of the more expensive items of equipment that are becoming increasingly necessary in food research to-day.

Immunochemistry

It is a sign of the deep interest that is now being shown throughout the scientific world in the chemical aspects of immunology that a distinguished group of scientists should have launched a new scientific publication—a journal of immunochemistry—under the title *Immunochemistry* (1, No. 1; April 1964. Annual subscription rates: (*A*) for libraries, government establishments, research laboratories, etc., £15 (40 dollars); (*B*) for individuals who place their orders directly with the publisher and certify that the journal is for their personal use, £5 (15 dollars). London and New York: Pergamon Press, 1964). The editor-in-chief is the eminent American immunochemist, Prof. Dan Campbell, of the California Institute of Technology, who is supported by three regional editors and a distinguished honorary editorial board of international character. The remarkable increase in the number of scientific publications falling within the field of immunochemistry has obviously stimulated the production of this new publication by the editors and the Pergamon Press. With the passage of time, no doubt the size of the volumes issued will increase so as to justify, on physical grounds alone, the segregation of immunochemistry from the broader subjects of immunology and biochemistry, of which it must remain a part and which, at the present time, are already covered by numerous national journals completely or largely devoted to the subject. Past experience has shown repeatedly that a new specialist journal, when once launched by a competent editorial board and an established publishing house, is assured of success because the appropriate scientists cannot afford to be without the new journal, and university libraries and research institutes must see to it that it is available for consultation. It is probable that the many international journals of biochemistry and/or immunology could easily contain the present output of papers on immunochemistry for some years to come. However, if in future papers are to be published in full, one could hazard a guess that the number of papers in this exciting field will increase considerably within the next few years. In order that they should not be buried in the great mass of biochemical and immunological publications, the editors have shown real foresight in starting a new journal at this phase in the development of immunochemistry.

An Engineering Buyers' Guide

The Engineer Buyers Guide, 1964, gives particulars of nearly 2,000 firms which advertise in *The Engineer* or in the *Guide*, and covers chemical plant, electrical equipment, engines, machine tools and accessories, sheet metal machinery and a wide range of general products (Pp. 1016. London: *The Engineer*, 1964. 10*s*.). Firms are listed under the headings of the products and, in addition, an address section gives the various addresses, telephone numbers and codes for each firm. Details of trade and technical associations, national undertakings and exhibitions are also given. There is also a list of United Kingdom agents for foreign firms. This *Guide* will be a useful addition to the reference books in any workshop or laboratory.

Seismology at Eskdalemuir Observatory

In July 1910, Prince Galitzin himself supervised the installation of Galitzin seismographs at Eskdalemuir observatory, Dumfriesshire, the Observatory having been established two years before, primarily so that geomagnetic recording could be obtained free from the artificial disturbances, mainly from electric trams and trains, increasingly affecting Kew Observatory. When geomagnetic recording finally ceased at Kew, in 1925, the Galitzins were transferred from Eskdalemuir to the basement of the main building at Kew from whence, to eliminate disturbance due to wind shaking the building, they were transferred, in 1937, to a new vault in the grounds. In recent years, owing partly to an increased interest in the science of seismology and partly to the need for distinguishing between man-made nuclear explosions and natural earthquakes, more sensitive seismographs have been devised and thus vaults in quiet localities with solid rock foundations are required. The Eskdalemuir area proved to be one of the best in the British Isles and was adopted by the U.K. Atomic Energy Authority as the site of their seismic array which is centred 4 km north-east of the Observatory. Following a recommendation of the International Seismological Survey that all countries work towards the ideal of a world network, having stations at intervals of about 1,000 km, and after a recommendation by the Council of the Royal Society, the Meteorological Office decided that Eskdalemuir Observatory should be developed as its main seismological recording base, with research facilities, in the United Kingdom. A start has now been made by the building of a new vault in the hill-side near the observatory and the installation therein of the standard seismograph system being presented by the U.S. Coast and Geodetic Survey to some 125 stations over the world. The equipment was installed in time to record the large Alaskan earthquake of 28 March 1964. It is appropriate that Eskdalemuir, the field station, is near to Edinburgh where there is the Royal Observatory Seismic Research Group and where there is also to be the International Seismological Research Centre and the International Seismological Summary Unit. There is space in the new vault for research workers generally to install seismic apparatus under test, and there will be available a shielded cable from the vault to a planned new surface laboratory where data recording and processing equipment can be located. It is expected that routine seismological recording with the older instruments will cease at Kew at the end of 1964, and that the *Kew Seismological Bulletin* will then be replaced by an *Eskdalemuir Bulletin*.

Memorial Lectures of the Institute of Physics and the Physical Society

The Institute of Physics and the Physical Society has announced the following arrangements for its memorial lectures during 1964: 1963 *Guthrie Lecture*, the postponed 1963 Guthrie Lecture entitled "Magnetic Processes in

Weak and Moderate Fields" will be delivered by Prof. L. F. Bates (University of Nottingham), in the Physics Department of the University of Nottingham on September 9; 1964 *Rutherford Memorial Lecture*, Dr. P. H. Fowler (University of Bristol) will give the 1963 Rutherford Memorial Lecture entitled "Pi-mesons versus Cancer ?" in the School of Physical Sciences, the University of Sussex, on September 9; 1964 *Guthrie Lecture*, the 1964 Guthrie Lecture entitled "Radio Telescopes" will be delivered by Prof. Martin Ryle (University of Cambridge) in the Physics Department of the University of Keele, on October 1. All three lectures will be held in conjunction with conferences, and for those not attending the conferences admission will be by ticket, obtainable from the Administration Assistant, the Institute of Physics and the Physical Society, 47 Belgrave Square, London, S.W.1.

Senior Fellowships for Short-term Visits to Australia

The Australian Academy of Science, from its J. Ellerton Becker Fund, is to provide substantial assistance to senior scientists to make short-term visits to Australia. Great flexibility is intended in the administration of the fellowship scheme; no restrictions are imposed with respect to nationality, occupation of the men to be appointed, or subject (within the natural sciences). The Academy welcomes enquiries from scientists of professorial standing or the equivalent who may wish to visit Australia in connexion with their own scientific researches or to confer with Australian scientists. Applicants are expected to have had prior correspondence with the relevant laboratories in Australia to ensure that their visit would be of advantage to scientists in Australia, as well as to the applicant. Fellows would normally be expected to participate in colloquia, and to deliver a limited number of lectures in one or more of the major cities of the Commonwealth. They would, however, largely determine their own programmes. A brief report is expected at the end of the visit. Maximum support will be on the basis of economy class return air fare and a subsistence allowance at the rate of £A5 per day. A minimum period of six weeks is desirable for any visit, and visits of longer duration would be welcomed. In special circumstances a minimum period of four weeks might be considered. Application forms for fellowships can be obtained from the Executive Secretary, Australian Academy of Science, Gordon Street, Canberra City, A.C.T., Australia. Applications will be considered and awards made quarterly; applications closing on January 31, April 30, July 31 and October 31 each year.

University News : London

At his request, Prof. P. M. S. Blackett will stand down as Pro-Rector of the Imperial College of Science and Technology at the end of the present academic year. Prof. O. A. Saunders has been appointed in his place as from October 1. Prof. Blackett will continue to hold a chair of physics. Promotions to senior lectureships at the Imperial College of Science and Technology are as follows: Mr. L. R. Barrett (chemical engineering and chemical technology); Mr. C. J. Carpenter (electrical engineering); Mr. R. G. Davies (zoology and applied entomology). Appointments to lectureships in the College are as follows: Dr. D. W. G. Ballentyne, Mr. R. S. Sidorowicz and Mr. R. W. Wilde (electrical engineering); Dr. D. E. Newland (mechanical engineering); Dr. J. M. Charap and Dr. S. Doniach (physics).

Newcastle upon Tyne

Mr. J. W. House, who is at present directing research schemes on "Rural Problems in North East England" for the Development Commission and "Migration and Mobility of Labour in North East England" for the Ministry of Labour, has been appointed to the second chair of geography. Appointments to lectureships are as follows: Dr. A. J. McComas (physiology); Dr. R. H. Stobbart (zoology); Dr. P. Gray (theoretical physics in the Department of Physics).

Southampton

Prof. J. E. G. Raymont, who has held the chair of zoology at Southampton since 1946, has been appointed to the chair of biological oceanography. Prof. Raymont will be head of the new Department of Zoology and Oceanography. Appointments to lectureships are as follows: A. F. E. Zagni (civil engineering); G. J. Rogers (electrical engineering); H. A. Kemhadjian and Dr. R. C. Smith (electronics); D. Harding, R. C. King and Dr. G. Lederer (mathematics); Miss P. Rothwell (physics); Dr. J. D. Burton (zoology and oceanography).

Announcements

Dr. Henri-Paul Koenig, at present a member of the staff of the National Research Council of Canada, has been appointed Scientific Counsellor at the Canadian Embassy in Paris. Dr. Koenig was previously professor of physics at Laval University and a past vice-president of the Canadian Association of Physicists. Dr. Koenig succeeds Dr. J. Gordon Malloch, who is returning to Canada and will retire shortly.

The Department of Scientific and Industrial Research has awarded a grant of £142,000 to the University of Southampton towards the cost of research on sound and vibration under the direction of Prof. E. J. Richards, professor of aeronautics and astronautics and director of the Institute of Sound and Vibration Research, for the four years ending July 31, 1967.

The summer congress of the Universities Federation for Animal Welfare will be held at Redland College, Bristol, during September 4–11. Further information can be obtained from the Universities Federation for Animal Welfare (Summer Congress), 7*a* Lamb's Conduit Passage, London, W.C.1.

A symposium on "High Temperature Inorganic Chemistry", arranged by the Inorganic Chemistry Division of the Chemical Institute of Canada, will be held at Carleton University, Ottawa, during September 2–4. Further information can be obtained from the Chemical Institute of Canada, 48 Rideau Street, Ottawa 2, Ontario.

An international summer course on "Some Physical Aspects of Oceanology in Shallow Seas", arranged by the Netherlands Universities Foundation for International Co-operation and sponsored by the North Atlantic Treaty Organization, will be held at Lunteren during September 1–18. Further information can be obtained from the Registrar, Netherlands Universities Foundation for International Co-operation, 27 Molenstraat, The Hague.

An international seminar for research and education in physics, sponsored by the Swedish Agency for International Assistance, the International Atomic Energy Agency and Unesco, will be held at the Institute of Physics, University of Uppsala, for one year commencing September 1. Forms of application and further information can be obtained from International Seminar, Institute of Physics, University of Uppsala, Uppsala.

A summer school in "Organic Spectroscopy", organized by the Royal Institute of Chemistry in collaboration with the Society for Analytical Chemistry, will be held at the School of Pharmacy, University of London, during September 6–12. The school will provide an organized and concise presentation of infra-red and nuclear magnetic resonance spectroscopy in terms of organic structures. Emphasis will be placed on fundamental principles and basic techniques. Further information can be obtained from the Royal Institute of Chemistry, 30 Russell Square, London, W.C.1.

GAS CHROMATOGRAPHY

An informal symposium organized by the Gas Chromatography Discussion Group of the Institute of Petroleum was held on April 7 at the Shell Centre, Waterloo, London, with Mr. C. S. G. Phillips in the chair. The symposium was preceded by the annual general meeting of the group followed by an introduction, on behalf of Shell, Ltd., by Lord Rothschild.

The first paper was given by Mr. J. C. Hawkes on "The Use of the Gas Density Meter for Process Monitoring and Control" in which he described the use of this detector for following the progress of vapour phase oxidation processes such as the production of maleic anhydride from benzene. Mr. Hawkes first listed the factors affecting the design of an instrument for applications of this sort. These were: (1) accuracy; (2) ease of calibration; (3) stability; (4) ease of maintenance; (5) facility for sample handling; (6) reliability; (7) provision of an output suitable for the control of the process. Passing on to a consideration of the detector itself, he said that the diameter of the orifice leading to the anemometer had an effect on the linearity of the detector. Enlargement of this orifice over a limited range increased both the linear range and the sensitivity. Increase of the carrier gas flow-rate through the cell, on the other hand, gave greater linear range without affecting the sensitivity, and by adjustment of these two parameters a detector having suitable characteristics could be obtained. A plot of gas flow-rate against thermocouple output rose sharply at first and then levelled out and, from a stability point of view, it was best to work in the level region where small changes in flow-rate would not affect the detector response. Other factors controlling the output of the detector were the nature and pressure of the carrier gas and its moisture content.

Mr. Hawkes next described a complete plant control system in which two density balances were utilized. The first of these was used alone as an on-stream detector to monitor continuously the input benzene concentration. In oxidation plants of this type the hydrocarbon reactant is carried through the system in a stream of air and this could be passed through the sample cell of the density balance to give a signal proportional to the benzene concentration. Process air from the same source, but containing no hydrocarbon, was used as reference gas, thus eliminating any response due to water in the carrier. The second detector was used with a column and sample loop to measure input hydrocarbon, output product and impurity concentrations. Use of a single chromatograph, with suitable valve system, for all these purposes avoided difficulties due to differences in sensitivity which might arise with more than one detector. Sample lines from the plant to the chromatograph were steam heated right up to the column oven. This was electrically heated with forced convection in order to achieve control to within 0·1° C with no temperature gradient. Pneumatically controlled solenoid valves were used for gas stream switching and these were normally automatically cam-operated by a programme unit. Results could be displayed on a recorder either as normal chromatograms or in compressed 'bar-graph' form. Concentrations were measured by peak height and, in order to obtain an accuracy within 0·1 per cent, it was necessary to maintain variables to within the following limits: gas flow-rate 0·3 c.c./min; oven temperature 0·1° C; gas pressure 0·4 mm; bridge current 0·002 amp. In order that sample switching and result presentation could be automatic it was also important that retention times of components did not vary by more than 1 sec. This required control of carrier flow-rate to within 1 c.c./min, column temperature within 0·3° C, and column pressure within 7 mm. Mr. Hawkes concluded by saying that he had had a number of instruments using density meters working for some time and had found this detector very satisfactory from the point of view of ease of calibration and stability. Other detectors, such as flame ionization, would, of course, give greater response, but for most of their applications the sensitivity of the density balance was quite adequate.

The second paper was given by Dr. C. S. F. Pine on the subject of "On-line p.p.m. Analysis by Gas Chromatography". He commenced by defining his field as that of direct measurement of substances present in vapour or liquid process streams at concentrations usually less than 100 p.p.m. Preconcentration techniques were generally unsuitable for on-line applications, but their use had become largely unnecessary due to the advent of ionization detectors.

On the use of in-line instruments by Imperial Chemical Industries, Ltd., Dr. Pine said that the first one had been installed in 1955 and used a katharometer detector for the determination of percentage amounts of mixed gaseous hydrocarbons. Their first p.p.m. instrument, installed in 1959, monitored hydrocarbons in oxygen over the range 0–3 p.p.m., sounding an alarm if the concentration rose above 2 p.p.m. This instrument used an argon ionization detector. Since this time instruments had been installed at the rate of about two per year, the earlier ones being home-made, but more recently some commercially produced instruments had also been used. The greatest advance in the development of in-line instruments during this time was the use of reliable automatic sampling valves for injection of liquids and gases. The type now widely employed was the linear movement sliding face valve developed by Imperial Chemical Industries, Ltd. Reasons for the spread of in-line instrumentation included its speed of analysis which was ideal for process control. Prevention of the formation of off-specification products had economic benefits in reducing the amount of re-purification necessary. In the intermediate stages of production, on-line analysis detected impurities which might be undesirable or dangerous in later stages.

Discussing the ways in which on-line chromatographs differ from their laboratory counterparts, Dr. Pine listed the following characteristics of control instruments: (*a*) fixed volume samples are used so that the recorder trace can be calibrated in terms of peak height; (*b*) multiple columns with switching and by-pass valves are used to reduce analysis time to a minimum; (*c*) column materials must be stable over a period of at least 12 months; (*d*) electrical circuits are arranged to show only signals from components of interest; (*e*) attenuators are used to adjust the scale range for each component and the recorder is usually started and stopped to give compact 'bar-graph' presentation; (*f*) programming units perform all the repetitive operations, thus necessitating stability of peak elution times; (*g*) lay-out and housing of the units are designed for easy sample handling and to comply with factory safety regulations; (*h*) on-line chromatographs must be designed to operate for long periods with a minimum of maintenance.

On-line p.p.m. analysis could be applied to most organic substances boiling below 300° C, but analysis of permanent gases was not practicable at the moment due to lack of a satisfactory detector. Concerning the problem of sample injection, Dr. Pine said that satisfactory sliding valves were now available from W. G. Pye, Ltd. With samples in the 1–20 µl. range the valve had sufficient heat capacity to act as an efficient flash vaporizer. Realizable peak height reproducibility was within about 1·5 per cent although the actual volumetric reproducibility of the valve was known to be better than 0·1 per cent in 5 µl. Failure of the sample to evaporate as a compact plug, among other factors, was thought to be responsible for this discrepancy. It would be preferable to work always with vapour samples, but if these were condensable complications arose with accurate pressure and temperature control. The sliding valves were also used, connected in a different manner, for other functions such as back-flushing and column switching. Difficulties often arose in the choice of a suitable stationary phase and in some cases multiple columns using different stationary phases were necessary. The greatest trouble usually arose from the large tailing peak due to the major constituent. If this was the last substance to be eluted time could often be saved by back-flushing it from the column after all the impurities had gone through. When some impurities followed the major constituent and were contaminated by its tail the position was more difficult. The best solution found was to collect the eluent over the period when it contained the impurities and to re-chromatograph this material on another column. The impurity peaks were then often completely resolved from that due to the now much reduced amount of major constituent. Preparation of columns for on-line p.p.m. work required that great care be taken to ensure as complete a removal as possible of volatile impurities and residual solvent. All the columns in present use were of the packed type as capillary columns had been found to lack sufficient long-term stability. In setting up these analysers all carrier gas pipework required to be thoroughly degreased and then baked out *in situ*, sometimes for some weeks, until contamination was reduced to a very low level.

Surveying the present position, Dr. Pine put forward a plea to manufacturers to provide more equipment for this field at a reasonable cost. Application engineering, normally supplied by the manufacturer, might well be left for at least the larger users to provide for themselves with consequent reduction in purchase price. The position was, he said, improving at least so far as American and Continental manufacturers were concerned. He concluded his paper by suggesting that future development might be aimed at increasing speeds of analysis, improving liquid handling techniques, collecting and publishing adequate retention data and developing linear and stable detectors which would extend the applicability of this field of gas chromatography.

Owing to the absence of Mr. J. Mawson, the paper on "Some General Aspects of Process Control with G.L.C. Analysers" could not be given, and it was left for Dr. H. J. Noebels of Beckman Instruments to put forward the view of the manufacturers in a contribution entitled "Applications of Industrial Gas Chromatographs to Process Monitoring and Control". He said that they had considerable experience in this field and that analysis of their instruments sold over the past year showed that 1 in 4 were equipped for continuous control of plant. The first chromatographs of this type were made in 1957, and since then about 2,000 instruments of all manufacturers had moved into the process field. Some six months ago Beckman produced an instrument which incorporated some new and important features. A major difference between process and laboratory instruments was that the latter were controlled by a competent operator who could take into account a number of factors such as varying base-lines. Control instruments, on the other hand, had to work completely alone practically continuously with perhaps, at the most, 2-h maintenance per month. The instrument must therefore be exact, automatic, dependable and capable of providing as short an analysis time as possible.

The last point became even more important when, as sometimes occurred, 5 min was taken for the sample to travel from its point of extraction from the plant stream to the analyser. A process instrument, Dr. Noebels said, must handle complicated streams and often was required to produce results expressed in a number of different ways. It might, for example, be required to estimate C_3, C_4 and C_5 compounds separately but to give a combined figure for C_6–C_{10} compounds. For this reason a considerable amount of stream switching was necessary. The valves utilized for this purpose were similar in design to those described by Dr. Pine and, when used for sample injection, had a lower limit of 1 µl. 'Teflon' was used in their construction for applications below 225° C, and they could be used at pressures of up to 350 lb./in.^{2}. Two types of detector were normally used: (1) four-element katharometer having a sensitivity such that full-scale deflexion was obtained with 50 p.p.m. of acetylene in ethylene; (2) flame ionization detector giving full-scale deflexion for 1 p.p.m. of acetylene in ethylene. Difficulty had been experienced in introducing flame detectors for plant control particularly in refineries, but their high dynamic range made them of great value for process monitoring applications. Dr. Noebels said that it was desirable to keep the number of controls on the front of the instrument as small as possible. Those which required occasional adjustment were mounted inside the case and pre-set, while repetitive operations such as gas flow switching, attenuation adjustment, etc., were carried out by a programme unit. This was normally of the type using magnetic tape but could be replaced by a cam-operated unit for those operators who desired a visual indication of the progress of the control cycle. Columns were heated by circulation of preheated air and required to have a life of at least six months with only a very slow change in retention times.

Eight basic column configurations were used: (1) single column; (2) single column with back-flush; (3) single column with back-flush and stripping: this elutes light compounds individually and the heavier ones as a group; (4) dual column: low boiling materials go through to a second column while high boiling compounds are detected after the first; (5) dual column with back-flush; (6) dual column with back-flush and stripping; (7) heart cut column: this was similar to the system described by Dr. Pine for chopping out a portion of the tail of a major peak; (8) 'flip-flop' column. This system comprised three similar sections designated the pre-splitter, storage and regrouping columns which were connected in series in the order given. It could be used for recombining a number of peaks when it was desired to estimate these together. Thus a sample containing substances eluting normally in the order A, B, C, D, etc., could be put on the column and allowed to run for a calculated time such that it was known that substance B had just entered the regrouping section. At this time fractions C, D and E could be at various points in the centre storage section, and if the flow through this part of the column were now reversed they would pass from it to the regrouping section in the reverse order (E, D, C). Fractions A and B would therefore emerge normally as separate peaks, but C, D and E, having the same distance to travel to the end of the column as they had each already travelled from the start, would recombine and would emerge as a single peak.

On presentation of results, Dr. Noebels said that 'bar-graph' readings were often insufficient and that a steady-state signal was useful for conversion to a pneumatic output for control of the plant. Such a signal could be obtained by amplification of the detector output and storage in capacitors, one for each component. Of actual analysis, 90 per cent was accomplished by peak height measurements, but integration was sometimes necessary. Features which made the gas chromatograph an ideal instrument for plant applications were its great speed (three components could be estimated in less than 1 min) and its high sensitivity. Applications had included such things as: (1) estimation of 0–50 p.p.m. of acetylene in benzene; (2) control of phthalic anhydride production; (3) determination of hydrochloric acid, chlorine and phosgene from 'Fluolube' on 'Teflon'; (4) determination of hydrogen in water in the range 0–5 p.p.m.; this estimation could be carried out in 5 min on a 50-µl. sample; (5) heart cut analysis of ethylene; (6) cascade control of distillation columns. He concluded by saying that generally a pay-off time of one year could be considered a good application of instrumentation.

C. D'Oyly-Watkins

PLACE OF BIOCHEMISTRY IN THE NEW UNIVERSITIES

At the Middlesex Hospital Medical School on April 16, the Biochemical Society held an evening discussion on "The Place of Biochemistry in the New Universities", a topic which aroused considerable interest and not a little feeling. In framing the discussion it had been agreed not to limit it strictly to the new universities but to include all universities in which biochemistry had only recently been introduced or was about to be taught.

Sir Rudolph Peters took the chair and, in the course of his opening remarks, pointed out that nowadays many aspects of biochemistry masqueraded under other titles. The new term 'molecular biology' had been introduced by Astbury and was, perhaps, valuable for getting money, but the claim that biochemistry only dealt with small molecules was just not true—we had always dealt with substances like proteins. With the present ramifications of biochemistry it was especially pertinent to discuss its role in the new universities.

Prof. R. A. Morton (Liverpool), under the title of "Biochemistry—Past and Present", traced the development of biochemistry with special reference to universities where the subject is now firmly established. The first department of biochemistry in Great Britain was founded at Liverpool in 1906, the inspiration of the department and of biochemistry in general at that time being derived from work on vitamins and nutrition. This and other departments were first set up in faculties of medicine, for it was from this direction that the need for teaching and research first arose. Very few honours courses in science faculties were started before 1939, but since the War the number of such courses had multiplied rapidly so that to-day most recruits to the subject have been trained as biochemists.

Over the years, the courses for medical, dental and veterinary students have changed and continue to do so. Although in the teaching, applications are not forgotten, they are subordinated to the need to expound the basic principles of biochemistry so that, for example, the clinical aspects of the subject come later from specialists.

Prof. Morton stressed that the biochemist should be competent in chemistry but must also have biological training and insight. Much had been achieved in the past, and no doubt would be in the future, by those who had detected, isolated and determined the structure of metabolites. Theories, for example, of photosynthesis or oxidative phosphorylation could be elegant even with an incomplete roll-call, but truer theories follow a full muster of the molecular species engaged—whether in biosynthesis or enzymatic mechanisms.

Biochemistry is now a central part of many curricula in biology. The sharp boundaries between sciences have gone; trespassing invokes only a shrug and territories are 'invaded' without apology. Chemistry, biochemistry and microbiology interpenetrate, and terms like genetics, biochemical pharmacology, neurobiochemistry and biochemical systematics all point to unification within diversity. This calls for psychological readjustment and reconstruction of teaching, organization and administration, on a scale easier to realize in a new university than an established one. There must be flexibility, perhaps, especially in M.Sc. courses. Prof. Morton emphasized that there is, however, a hard core of biochemistry which cannot safely be watered down.

In a period of expansion the penury of the past was easily forgotten, but it may be more difficult to sustain the peculiar excellence which raises university studies above the trivial.

In the subsequent discussion, Prof. J. N. Davidson (Glasgow) pointed out that biochemistry has tended always to suffer from being a hybrid subject. It grew up under the wing of physiology in most universities (occasionally under pathology) and only within recent years has begun to lead an adult independent life as a scientific discipline in its own right, rather than merely as a subdivision of some other subject. However, there are now disturbing trends. The chemists, who used to despise it, are now beginning to realize its importance and are tending to say that biochemistry should certainly be developed in all universities, but only as part of the chemistry department.

The biologists are belatedly taking an interest in biochemistry and are tending to follow the same unfortunate course as the chemists. By showing less interest in taxonomy and ecology and a greater interest in cell biology, they have realized that they cannot go very far in any biological discipline without biochemical help and they are therefore tending to say biochemistry must certainly be developed, but only as a part of a biological department.

Prof. Davidson went on to say that he was all in favour of breaking down barriers between sciences and of having the utmost collaboration between representatives of different disciplines, but was utterly opposed to the trend that biochemists may develop into mere laboratory assistants helping 'big brother biologist' to solve his problems.

Prof. E. A. Dawes (Hull) then presented the results of a survey he had made on present and future developments in Britain with particular reference to the place of biochemistry in the development of biological sciences in the new universities. There are seven new universities in England of which five have either planned or already initiated biological studies, and a sixth has it under active consideration. In Scotland, at the new University of Strathclyde, existing biology departments of the Glasgow Royal College of Science and Technology are to become part of a School of Biological Sciences, housed together in a separate new building and offering honours degrees in biochemistry, food science, biology, microbiology and general biological sciences.

The development of biological sciences in the new English universities has, without exception, followed the suggestion of the *ad hoc* Committee of the Royal Society (*Ann. Rep. Advisory Council on Scientific Policy, 1961–62*, H.M.S.O., 1963) that multi-professorial departments be created and under the one roof a variety of different biological disciplines be represented. East Anglia, at present, is the only school to have started teaching along these lines; Sussex and York both commence operations in October 1965, while Kent expects to do so in 1966.

At Sussex advanced teaching and research are being arranged round a number of research groups each headed by a senior member of staff; the units at present envisaged include animal physiology, biochemistry, microbiology and plant physiology, and the research activities of most of them will be strongly biochemical in outlook. The three-year honours course in biology will precede a fourth-year course of advanced study leading to an M.Sc. degree. At York fairly close co-operation between the departments of biology and chemistry is planned and the three-year honours course in biology will include specialization in the third year; biochemistry may be selected as one of the topics for this. Clearly, courses in the new departments are in the process of evolution and present information is of a provisional nature. It was evident, however, that belief in the necessity for a fourth-year M.Sc. course was universal in the new universities offering degrees in biology. To conclude, Prof. Dawes mentioned the newly created professorial departments in universities which do not have a medical school—Leicester, Southampton and Hull—and gave a brief description of the honours course in his own Department which includes a one-year course in cell biology, two years of chemistry and biochemistry in all three years.

In discussion, Prof. J. F. Sutcliffe amplified the plans for Sussex and emphasized the importance of the biochemistry unit to their scheme. Other speakers expressed misgivings on the brevity of the basic chemistry courses in many of the biological sciences syllabuses and pointed to the flimsy foundations on which the biochemical content of the course would have to be built. The chairman stressed that all biochemists should be taught to work with small amounts of substances.

Prof. H. L. Kornberg (Leicester) outlined the development of biochemistry within the framework of a three-year course leading to a degree in cell biology, and discussed the reasons for this approach rather than the more conventional honours course in biochemistry. At Leicester it was felt that, at the undergraduate level, biochemistry might be most effective as the central theme of an inter-departmental degree course jointly planned and executed chiefly, if not exclusively, by specialists in biochemistry, genetics and physiology, but that chemistry to an advanced level, and other physical and biological specialities to less-advanced levels, would also form indispensable parts of the degree structure. Such a course would provide graduates suitable for teaching at the secondary modern school level, Civil Service experimental officer grade, or the equivalent level in hospital or industry. More able students would take one-year M.Sc. courses in the particular speciality that has aroused their interests and this would be a prelude to the orthodox three-year period leading to a Ph.D. The flexibility which this proposed course, planned for 1967, would confer, by virtue of the wide biological interests of the academic staff concerned, was emphasized.

Prof. Kornberg then described plans for the new School of Biology at Leicester, which, with more than 90,000 sq. ft. of usable space, will house not only all the existing biological science departments but possibly also biological specialities as yet unborn. A department of genetics has recently been established and similar developments in general physiology are to occur, while the appointment of Dr. E. R. Redfearn to a second chair of biochemistry at Leicester had just been made.

The development of biological chemistry in the University of Manchester was described by Prof. A. J. Birch. An honours school of biological chemistry was established in 1961 in the Faculty of Science with studies extending over three years and with considerable emphasis on chemistry and biology. At present, this is achieved by exclusion of biochemistry from the first-year courses, and the intermediate examination at the end of the first session includes chemistry, physiology and either botany or zoology. The first two terms of the second year are divided equally between chemistry and biochemistry, both of which are included in the Part I examination held at the end of the Easter vacation of the second session. Biochemistry occupies the whole of the students' time during the summer term of the second year (this being a full teaching term) and throughout the third year, with the exception that during the third year students attend short ancillary courses chosen from a wide range.

A full tutorial system is operated during the summer term of the second year and throughout the third year, and less frequently in the earlier parts of the course. It is hoped in future to extend the full tutorial system to all three years. Further developments planned for the future include an introductory biochemical course in the first year and it is hoped that a single, fully integrated course in biology may be established.

In planning the courses for the new honours degree, the aim has been to give students a thorough understanding of the chemical and biological bases of the subject and a good appreciation of general biochemistry without emphasizing any one specialized aspect. Dr. G. R. Barker elaborated on some aspects of the course.

The final speaker was Prof. T. A. Bennet-Clark (Norwich), who discussed the role of biochemistry within a school of biology and described developments at East Anglia, where a special feature is being made of the biological sciences. Biochemistry is fundamental and must be incorporated in the courses, but this could only be achieved by elimination of dead wood from the more classical aspects of the biological parts of the curriculum. A critical problem is that of recruitment, for the ideal aspirant should have a good background of mathematics, physics and chemistry in addition to his biology; this poses almost insuperable difficulties in the schools and forces the university school of biology to teach in the first year appropriate aspects of mathematics and physics.

A three-year undergraduate course is operated at Norwich which provides during the first two years, in addition to chemistry, mathematics and physics, a background having a general physiological and genetical basis. The third year permits specialization in which three options are selected from a present list of eight, of which (1) biochemistry and (2) biophysics and biophysical chemistry are two. A fourth-year M.Sc. course permits further specialization: a course in biophysics is run by Prof. J. Dainty and, in the future, a course in food science will be available. Prof. Bennet-Clark made the point that a three-year first degree course is by no means an adequate training for any career and hence the desirability of having a fourth-year M.Sc. course.

Sir Rudolph Peters then declared the meeting open for general discussion and some lively comments ensued. Concern was expressed that the plans for the new universities did not include strong biochemistry departments in which the teaching was securely based on chemistry. Latent fears for the emergence of a breed of 'tame biochemists' were in evidence.

Dr. G. R. Barker aroused much interest and support for his proposal that a new advanced-level subject 'Physics with Mathematics' should be instituted by the examining boards. Such a paper would go a long way towards solving the problem of university entrance requirements for the biological sciences. The meeting passed a resolution that the Committee of the Biochemical Society consider whether the Society might approach the examining boards in this connexion. Prof. Morton said how important it was that faith should be kept with the school teachers so that they knew precisely what the university biologists wanted of their pupils.

The meeting was universally adjudged to have been a timely and instructive one, and the large attendance reflected the widespread interest in developments in the new universities.

E. A. DAWES

AGRICULTURAL SOIL SCIENCE

TEN years have elapsed since the popular Easter School in Agricultural Science was inaugurated at the School of Agriculture in the University of Nottingham. The eleventh meeting, which was held during March 23–26, was marked by a symposium and colloquium on "Experimental Pedology". Some 130 scientists, experts in a wide range of disciplines and assembled from the British Isles, Europe, Israel, the British Commonwealth and the United States, testified to the general interest in soil science and to the particular concern for that aspect of the subject dealing with the genesis, properties and classification of the soil profile.

After a welcome to the University from Mr. B. L. Hallward, the vice-chancellor, the delegates settled down to a programme developing logically from organic geochemistry and the chemistry of rock surfaces through the organic and inorganic agencies of soil profile development studied *in situ*, in the laboratory and by model simulating processes, to the final analysis of experimental pedology in relation to soil classification.

The assessment of release and redistribution of major and trace elements in weathering rocks, in the soil profile and of their loss in drainage water has always been at the basis of soil research. The construction of a rough balance sheet from such data can be instructive and informative, but its value is greatly enhanced when the agencies responsible for the changes can be identified qualitatively and quantitatively.

The symposium not only illustrated the enormous wealth of information that exists on the results of soil changes but also the dearth of precise knowledge of the processes and their dynamics. Too little is known of the movement of either simple ions or of more complex substances, nor do we yet know enough about the natural processes of clay formation or of the precise roles of living organisms or their products in the development of soils. Discussion of the kind provided by this School serves an excellent purpose by directing attention to these needs and should serve in turn to kindle the fire of fresh ideas and extend the mind to further effort.

This stimulating and provocative symposium was noteworthy for its unobtrusive yet skilful organization, tribute for which must be paid to Prof. Hallsworth and his many helpers. His forthcoming departure to the Commonwealth Scientific and Industrial Research Organization (*Nature*, 199, 1237; 1964) carries both our good wishes and thanks for his inspiration of the Schools.

R. I. DAVIES

BRITISH COAL UTILIZATION RESEARCH ASSOCIATION

THE annual report for 1963 of the British Coal Utilization Research Association*, which includes a list of publications and of staff, records a total staff at the end of the year of 67 scientists, 109 research officers and research assistants, 47 in clerical and administrative grades, and 90 in industrial grades. An extensive survey was completed of the behaviour of a variety of types of coals with a wide range of ash-fusion characteristics, in an attempt to relate coal type and ash composition with the formation of clinker and slag in shell boilers. There was very little clinker formation with any of the coals but sufficient slag on the ignition arch to attempt corelations. The opportunity was taken to investigate the formation of deposits on end-tube plates which, with some coals, can be very troublesome.

In domestic heating, the first of four main programmes was to try to improve the amenities and performance of the conventional central heating boiler fired with smokeless fuel. The second programme is to try to devise a means of burning bituminous coals smokelessly in a central heating boiler; the third, to design a reliable and cheap heat meter; and the fourth, to obtain reliable information on the amount of smoke emitted from domestic appliances for a range of fuels. Investigations of mineral deposits and corrosion in water-tube boilers are increasingly directed to problems which may arise in future in the large power-station boilers operating at very high steam temperatures and pressures. Four proprietary alloy steels of different composition have been tested above 600° C in the biggest of the three laboratory combustors when using a range of coals including the normal test fuel of high chlorine content, and further extensive trials have been carried out on the town-gas-fire combustor.

Much work on slagging gasification during the year has been concerned with filling gaps in the knowledge of slag formation and behaviour and other facets of the operation of the slagging fixed-bed process. Confirmatory laboratory tests in the high-temperature viscometer have shown that, where refractory mineral matter is being dissolved in a slag, the apparent viscosity may attain a value several times that of the viscosity of the homogeneous slag that is finally formed. Investigations have been made into the changes of the chemical composition of slags under particular operating conditions, and particularly of the volatilization of silica and of the loss of iron. Systematic investigation of the slagging properties of the ashes of British coals was completed during the year, and some attention was also directed to the crystallization properties of the slags.

Basic investigations, during the year, of combustion and gasification were directed at exploring the phenomena of pre-ignition heating and the devolatilization of pulverized fuel particles in the laminar flow furnace. Measurement of the thermal conductivities and diffusivities of coals of temperatures up to 900° C has been completed. In observing the structure and reactivity of reactor graphites, comparisons have been made of the porous structure parameters measured at high and at room temperatures, and the structure of graphites has been further examined before and after their oxidation. More fundamental investigations of the chemical structure of coals have thrown further light on the distribution of groups containing hydrogen, and particularly the differences in fractions of aromatic hydrogen and of hydrogen in methylene groups in coals of different ranks. A two-pronged attack on the mechanism of decomposition in the coking temperature range has been further advanced and, from now on, basic investigations of the physical and chemical structure of coal will be directed more to understanding the reactions that occur in various combustion systems.

Fundamental investigations of simple breakages in commercial mills have been greatly advanced during the year. The examination of the stress distribution in thin particles loaded in a model of a ring-mill using photoelastic techniques shows that the primary failure occurs along lines of maximum tensile stress. The distribution of mineral matter in samples of pulverized fuel has also been examined.

THE ARTHUR D. LITTLE RESEARCH INSTITUTE

IN the annual report for 1963 of the Arthur D. Little Research Institute, Dr. F. N. Woodward, the director, reviews some of the outstanding developments in the first seven years operation of the Institute *. These include the work on interaction between certain metals and water at very high temperature, hydrogen embrittlement investigations, which appear to be revealing at least one pickling method which could safely be applied to very strong steels after heat treatment, and tempering without causing hydrogen embrittlement.

Fundamental investigations of the release of corrosive vapours from wood under tropical conditions have given a technique which appears to be capable of reducing significantly the corrosiveness of kiln-dried woods. Observations on the chemical modification of cotton have given a technique for increasing crease-resistance, and work on the chemistry of ethylene sulphide has also yielded patentable techniques and products. Two basic investigations of potential long-term significance are concerned with the crystallization and properties of high polymers and with gaining an understanding of photoconductivity in organic compounds generally and polymers in particular.

In the Biochemistry and Biophysics Division, wheat proteins and anti-tubercular factors in milk whey received considerable attention, while the work on peat isolates of industrial value was expanded and preliminary work on the fractionation of inorganic polyphosphates carried out. In carbohydrate chemistry, several promising new polymers were prepared from glucose and its derivatives and the principle of co-polymerizing small amounts of carbohydrate with cheap, readily-available monomers. to give reactive co-polymers, has been demonstrated, These afford an easy route for introducing reactive groups to improve the dyeing properties and hydrophilic groups to improve the water-adsorptive power of conventional man-made fibres. The investigation of the emission of corrosive vapours from wood continued for a third year and methods for the analysis, by gas liquid chromatography, of the volatile acids and neutral compounds of wood have been worked out and applied to the assay vapours arising from the exposure of wood-shavings to high humidity and tropical temperatures.

In sulphur chemistry, white crystalline polymers have been prepared from ethylene sulphide; mercaptans have been found to react with ethylene sulphide to give products which are also mercaptans and which further react with ethylene sulphide. In physical-organic chemistry, an extensive search has been made for high-temperature-resistant materials in organic, organo-metallic and inorganic chemistry, while the physical chemistry section has been mainly concerned with the crystallization and properties of polymeric materials.

Recently, facilities have been developed for investigating the electrical properties of materials. In metallurgy, the reaction between metals and water vapour up to 1,500° C and above has been further investigated for aluminium and aluminium–uranium alloys and zircaloy-2. The investigation of the adhesion between molten glass and metals has been continued in order to improve understanding of the fundamental principles governing sticking between hot glasses and a metal mould while the glass is being blown to shape during manufacture of glassware.

LUMINESCENCE OF ENSTATITE ACHONDRITE METEORITES

By C. J. DERHAM*, Dr. J. E. GEAKE and G. WALKER

Department of Physics, Manchester College of Science and Technology

WE recently reported the red luminescence of three meteorites of the enstatite achondrite type under proton excitation[1], and are now able to give some further information, including revised estimates of the radiant efficiency.

Our published spectrum for each meteorite shows a weak blue peak at about 4000 Å and a strong red peak at about 6700 Å (for example, Fig. 1), but with different red/blue peak intensity ratios for the three meteorites; we afterwards found that the differences were just as great between different samples of the same meteorite as between the three different ones. This suggested that two separate constituents of an inhomogeneous mixture were giving the red and blue luminescence, respectively. We then concentrated mainly on the Bustee meteorite, and a crushed sample was separated, by visual appearance under a microscope, into its main constituents. These were identified as follows: white enstatite ($MgSiO_3$), the main constituent; diopside ($CaMgSi_2O_6$), present as grey grains showing exsolution lamellæ of enstatite; brown crystalline oldhamite (CaS); and finally osbornite (TiN), present as a few minute golden octahedral crystals †. The latter two minerals are only known in meteorites, and do not occur in terrestrial rocks. These observed minerals agree with the known constituents of this meteorite[2] We then investigated the luminescence behaviour of each constituent separately, under proton excitation. The enstatite part was found to give a spectrum like that already found for samples of the mixture. The diopside luminesced weakly, if at all—it was difficult to free it from enstatite, and the resulting spectrum was a weak version of the enstatite one, with no additional features. It was, therefore, probably just the spectrum of the enstatite contamination. The oldhamite constituent, which was only present in small quantities, also showed the spectrum of residual enstatite, but with an additional yellow peak at about 5800 Å. This peak is not usually evident in the spectrum of the mixture, probably because of the small amount of this substance present. Also, this constituent was found to damage very quickly, and would not contribute for long to the spectrum of the mixture. A laboratory sample of CaS was found to show the same yellow peak, and also to damage rapidly. There was insufficient osbornite to obtain a spectrum, but when a few crystals of it were observed visually under proton excitation no luminescence was seen.

---

* Now at Barnet College of Further Education.

† We also found osbornite crystals in a sample of the Bishopville meteorite; this mineral has not, so far as we know, previously been reported anywhere except in the Bustee meteorite and its presence further emphasizes the great similarity between these two meteorites.

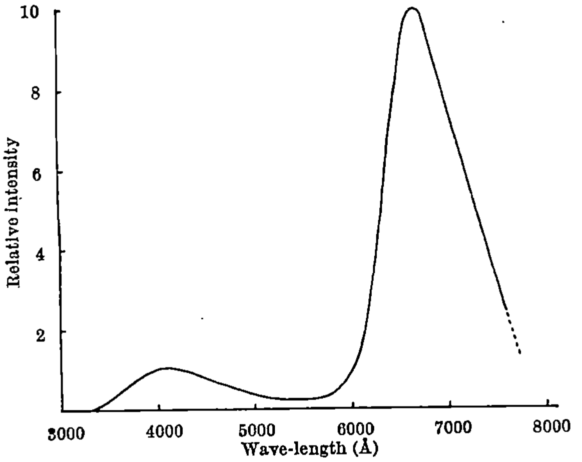

Fig. 1. The luminescence emission spectrum of a dust sample from the Bustee meteorite under 40-keV proton excitation

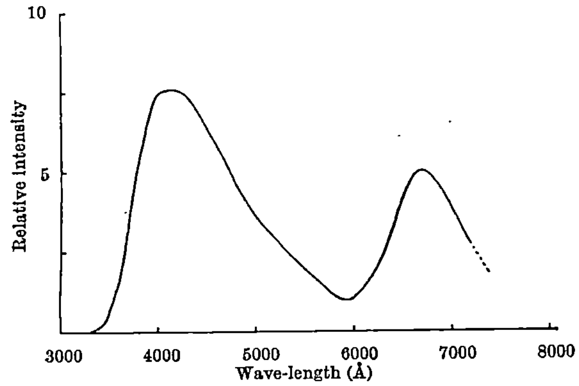

Fig. 2. The spectrum of the 'blue' constituent of Bustee

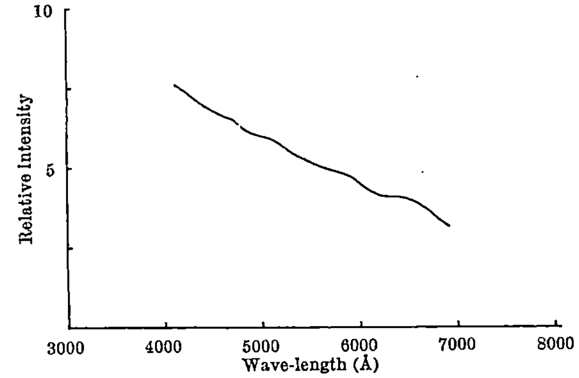

Fig. 3. The luminescence emission spectrum of Bustee under ultra-violet excitation

We conclude that the enstatite is probably responsible for all the observed luminescence. It is interesting to note that Garlick[3] has suggested, from a study of the published luminescence spectra of synthetic phosphors, that the red peak of the luminescence we observed was probably due to $MgSiO_3$ with manganese present as an impurity. The blue peak has not yet been explained.

However, it appeared that the enstatite was producing both the red and the blue peaks, whereas the variability of the red/blue peak intensity ratio suggested that two separate constituents were responsible. In an attempt to resolve this we then observed visually a mixed sample of the crushed meteorite, under proton excitation. It was seen that there were indeed some grains luminescing red and a smaller number luminescing blue (and some with a mixture of these colours). By noting their positions, the most distinctly 'red' and 'blue' grains were then separated out; the luminescence spectra of a crushed 'red' grain and a crushed 'blue' grain were then obtained separately. The 'red' grain gave a spectrum which was much the same as that for an average sample of the meteorite as a whole, with a slightly weaker blue peak; the spectrum of the 'blue' grain is shown in Fig. 2. The two spectra thus show red and blue main peaks, respectively, but each shows a certain amount of the other colour. The efficiency of the 'blue' constituent is about the same as that of the 'red' one, but its contribution to the total emission is small because it is only present as a small proportion of the mixture. X-ray powder analysis showed both grains to be orthoenstatite.

Later these observations were reinforced by obtaining a thin section of the Bustee meteorite, so that it could be observed visually under proton excitation with its constituents in their original configuration. It was found to luminesce red over most of its area, but with one small zone bright blue. When the section was transferred to a microscope, this 'blue' area appeared to be part of an enstatite region, but with no consistent differences in appearance as compared with its 'red' surroundings.

We conclude that while the enstatite constituent of this meteorite is responsible for its luminescence, it may luminesce either predominantly red or predominantly blue, depending on some factor as yet unknown. Investigation of this continues. We find, however, that samples of the meteorite as a whole always luminesce predominantly red, because the blue part is only present as a small proportion.

In our earlier communication[1] we gave a rough estimate of 20 per cent for the radiant efficiency of the meteoritic material, by comparing it with a readily available phosphor—ZnCdS–Ag, in the form of 'Sirius' screen. We have since been able to test this by comparison with other known phosphors, kindly supplied by Prof. G. F. J. Garlick. These include ZnS–Ag which emits in the blue, Zn_2SiO–Mn a green emitter, and $MgSiO_3$–Mn, the red emitter mentioned above. Efficiency figures for these phosphors under proton excitation do not seem to be available, but Bril and Klasens[4] give efficiencies under excitation by 20-keV electrons as follows: ZnS–Ag, 21 per cent; Zn_2SiO_4–Mn, 8·5 per cent; $MgSiO_3$–Mn, 6 per cent. We have now compared these phosphors with each other and with the meteoritic material under 40-keV proton excitation, with the same beam conditions. The relative emission efficiencies have been calculated from the relative intensities and integrated areas of the corrected spectra; we find them to be related as follows: ZnS–Ag : Zn_2SiO_4–Mn : $MgSiO_3$–Mn $= 2 : 1 : \frac{1}{4}$. The first two of these are relatively in rough agreement with the electron figures, whereas the $MgSiO_3$–Mn is low by a factor of about 3 compared with the other two. This may be because the relative efficiencies of these phosphors really are different under proton as compared with electron excitation, or because of sample variability.

The efficiency of the meteoritic material was found to be about one-sixth of that for $MgSiO_3$–Mn, which gives an efficiency ranging from just under 0·5 to about 1 per cent, depending on which phosphor one compares it with.

Of the meteoritic material we now find samples of Khor Temiki to be generally more efficient than Bustee or Bishopville, although variation by factors 2 or 3 from sample to sample is common. The brightness of the emission is also seen to vary from place to place on the dust samples, and the brightest parts may well have an efficiency consistent with its identification as $MgSiO_3$–Mn[3], which is itself one of the most efficient of the known red-emitting phosphors. The meteoritic material differed from this phosphor in showing no visible afterglow, presumably due to impurities.

We now conclude that although our original comparison with ZnCdS–Ag was instrumentally correct, the figure we quoted for the efficiency of this phosphor was too high.

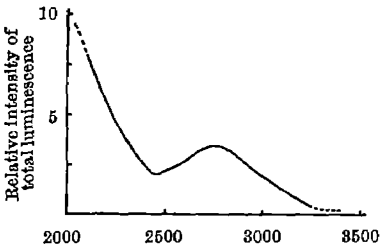

Fig. 4

The discrepancy seems to be due to the rapidity with which this material damages under proton bombardment. We find other phosphors to damage slowly, and we allow for this; however, the efficiency of ZnCdS–Ag is found to fall by a factor of 10 in the first 90 sec, for a typical beam energy and current (40 keV, 0·2 μamp). This was only revealed when we completed a sample-holding turret which enables four samples to be loaded at once and irradiated alternately without disturbing the vacuum or the proton beam. The intention was to permit more reliable comparisons of sample efficiencies; but it also means that the beam can be set up on one target, and the luminescence emission of the others can then be recorded right from the instant of first exposure. Any rapid initial damage is then easily seen. We conclude that previously our ZnCdS–Ag samples had always been appreciably damaged while the beam was being positioned and adjusted, and that the efficiency by the time we came to make measurements was usually less than 1 per cent. One of the other comparison phosphors, ZnS–Ag, was also found to damage rapidly, and it has already been mentioned that the CaS constituent of the meteoritic material damaged rapidly. It is interesting that all three of these materials are sulphides. In contrast to this very rapid damage, we find that the main material of the Bustee meteorite takes about 4 h, under the same beam conditions, for its efficiency to drop by a factor of about 10. We also find that it is possible to produce almost complete recovery of Bustee samples by heating. Investigation of this recovery process continues, as it is clearly of interest in considering the possibility of phosphors continuing to work on the lunar surface.

In considering the relevance of this meteoritic luminescence to that of the Moon, it is of interest to know the effect of different types and energies of excitation on the luminescence emission. Samples of Bustee dust were therefore excited in several different ways.

In our apparatus we can irradiate samples with protons of energies from 5 keV to more than 100 keV. We find the spectral profile of a sample of Bustee dust to be the same over this range of energies (Fig. 1), with an overall intensity roughly proportional both to accelerator voltage and to beam current. However, under ultra-violet excitation (mainly 2537 Å) the luminescence is quite different; it is almost white in colour, with the spectral profile shown in Fig. 3, and a very low efficiency—about 1/100th of that for proton excitation. The relative effectiveness of different ultra-violet wave-lengths in producing luminescence is shown in Fig. 4; this was found by recording, with a photomultiplier, the total luminescence emission from a sample under excitation by the output of a calibrated monochromator which was scanned in wave-length. The source was a deuterium lamp, and a Wratten *2B* filter in front of the photomultiplier absorbed any ultra-violet reflected by the sample. The peak of effectiveness appears to lie below 2000 Å.

We have also been able to observe visually the luminescence produced by several other sources of excitation; in each case it was red, and we estimated that both the colour and the relative efficiency appeared to be about the same as that seen under excitation by our low-energy proton beam. The excitation sources tried were: (1) protons at 2 MeV and 4 MeV from a Van der Graaff generator; (2) electrons from 5 keV to 40 keV; (3) X-rays, from a tube with a copper anode, run at 40 kV, giving a peak at about 1·5 Å and a continuum extending to a few Å. There appears to be an energy threshold in the region we are unable to investigate, between 2000 Å and a few Å, at which the low-efficiency white luminescence changes to high-efficiency red luminescence.

We thank Prof. W. S. MacKenzie for his geological help and advice and for carrying out the X-ray powder analysis. We also thank the British Museum (Natural History) for the loan of the meteorite samples; also Dr. J. M. Calvert for the use of the Van der Graaff generator, Mr. J. B. Shepherd for help with the electron excitation, Mr. W. Hughes for help with the X-ray excitation, and Mr. J. McConnell for help in constructing the apparatus. This work was sponsored by the U.S. Air Force Cambridge Research Laboratories, under contract *AF* 61(052)–379 through the European Office of Aerospace Research, U.S. Air Force.

AN ELECTRICALLY CHARGED TORQUE PENDULUM

By DR. ERWIN J. SAXL
Pin Hill, Harvard, Mass.

USING precisely timed parts of each period of an oscillating torque pendulum, a determination of individual short-time events was made in sequence.

The disk of the torque pendulum with which the subsequent observations were made is suspended from an isoelastic wire, the modulus of which is constant to 0·5 parts in 10^6/deg. C. Within the multiple enclosures, the temperature was maintained to ± 0·5 deg. C. The elastic restoring force of the wire remains, therefore, constant; only the difference is shown that is produced due to the slight winding-up and winding-down of the rotating pendulum. The pendulum oscillates in a Faraday cage which can be charged electrically together with the pendulum.

The disk is set automatically for each swing by attracting it electro-magnetically against a stop and holding it there by means of a time-delay for a pre-set length of time prior to release. This rest period frees it from the influence of ambients such as parastic oscillations of mechanical nature, eliminates the influence of the Earth's precession and restores the potential mechanical energy of the pendulum quantitatively for each swing. A mirror is attached to the mounting of the disk in a manner similar to a galvanometer.

Part of each period was timed by photoelectrically gating the output of a crystal controlled oscillator (which is precise to 3·5 parts in 10^{-8} sec) after the release from the stop and while the disk rotates at a position about midway between release and return where the speed of the disk approaches maximum. The time is measured during a part of the total cycle and includes both clockwise and counter-clockwise rotation. The beam of light starts the electronic counter on its clockwise motion and stops it on its counter-clockwise return. Direct digital printing is obtained without analog-to-digital conversion since the readout constitutes elapsed time. This simplifies rapid and accurate recording and facilitates input into data-handling systems.

Unexpected phenomena were noted as follows:

(1) When the pendulum was charged electrically with different, carefully controlled electro-static voltages (together with its equipotential shields), it was observed that positive and negative charges caused different delays (Fig. 1). A positive charge caused the pendulum to rotate slower, as a rule, than when the pendulum was charged negatively. The grounded pendulum swung fastest. (There are exceptions to this rule at times.)

(2) The time of swing follows in first approximation a square law (Fig. 2) with a small, negative bias. In view of this asymmetry there must exist, therefore, effects in addition to the usual eddy current damping since the latter would cause a symmetrical time delay.

(3) There exist differences between the influence of voltage on the pendulum at different times. While consistent within themselves, there may be one time-delay in spring and another one in mid-summer. Diurnal as well as seasonal variations were found.

(4) Unusual variations of the pendulum period were noted particularly during solar and lunar eclipses (Fig. 3).

In the foregoing precise determinations the influence of seisms, microseisms and changes in the Earth's magnetic flux was eliminated as was the influence of temperature, barometric pressure (and thus weight of the mass of air), humidity and other ambients. Possible variations in the electric supply voltage are limited to less than one part in 10,000.

The signal-to-noise ratio of the instrumentation (as shown in Fig. 1) is but a small fraction of the observed significant values.

The phenomena described here seem to go beyond what could be legitimately calculated from an extrapolation of present theory.

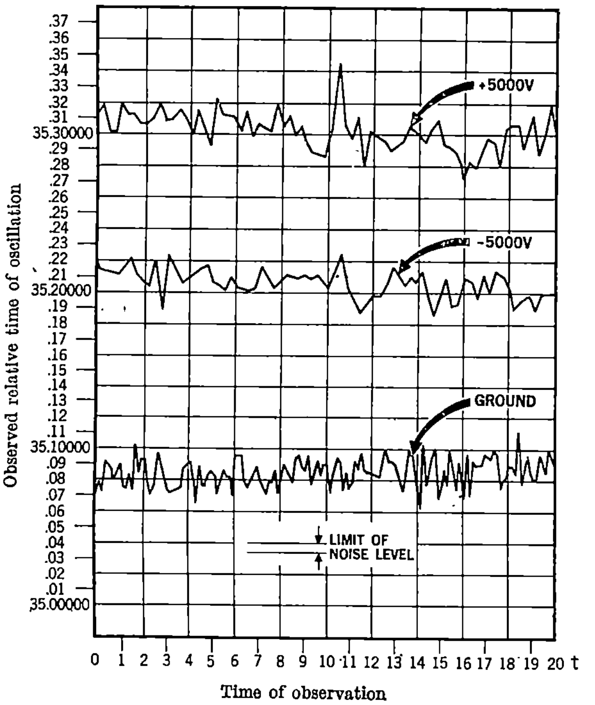

Fig. 1. Time delay of a pendulum when grounded and when charged positively and negatively with 5,000 V d.c.

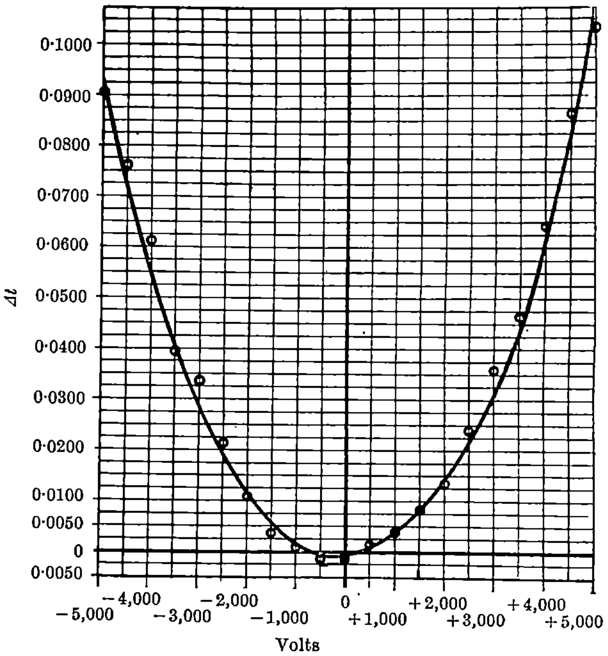

Fig. 2. Voltage versus period

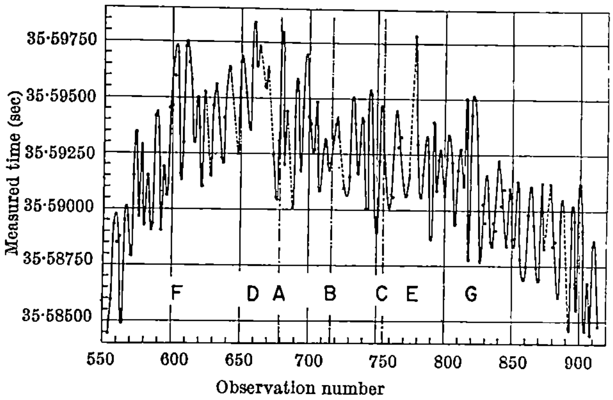

Fig. 3. Record of timing of the grounded torque pendulum during lunar eclipse of March 13, 1960

Referring to Fig. 1, it should be noted that the automatic cycle of observations, taken at the different voltages and ground, took place according to the following schedule: positive, ground, negative, ground, positive, ground and so forth in rotation. Each observation constitutes an individual determination. It is separated from the next one by the period of dwell (about 20 sec) on the resetting location, during which time all the cycling and voltage-changing operations occur automatically.

It is significant, therefore, that the deviations shown on the recordings, as made with the +, ground and − potentials, show a high degree of synchronicity despite the fact that one measurement is separated from the next one by more than 1 min. Whatever factors influenced the delay in the pendulum's period, they repeated themselves independently on consecutive measurements. 'Noise' would not do so.

Each point of the voltage-versus-period curve (Fig. 2) was determined at least 50 times and least squares taken for each point shown. The accuracy of the readings taken for each point therefore exceeds changes of the time of the pendulum oscillation due to its electro-static charge.

Consideration should also be given to such facts as, for example, those shown in the recordings taken during the lunar eclipse (Fig. 3). Herein the points of registration lie repeatedly on a harmonious curve with reference to their preceding ones as well as the subsequent ones thereafter. This exceeds the probability of a random occurrence.

The physicist hesitates to form a working hypothesis for such observations. Having accounted carefully, however, for all other influences, he is driven reluctantly to the conclusion that there may exist variations in *g* even if such cannot be noted with grounded, quasi-stationary instruments. These new effects may become noticeable if geo-gravitic flux-lines are cut dynamically and electrically charged apparatus is used.

When working as a post-doctoral student with Einstein, we discussed the possibility that there were interrelations between electricity, inertial mass and gravitation. These experimental results make me wonder whether they may properly be so interpreted.

Thousands of careful observations made under reproducible conditions, and records taken for more than ten years, indicate the possibility of significant short-time variations when measured dynamically with a conductive object rotating at an angle of 90° to its suspension which latter coincides with the geo-gravitic vertical.

These deviations were found with a torque pendulum but not with conventional pendulums of Kater's type and the usual gravity meters operating under equivalent conditions.

Apart from the foregoing phenomena, the precise torque pendulum has many other applications. One of them is a seismograph of ultra-long period. When charged electrically, it constitutes also a means for the recording of other phenomena the electric parameters of which have scarcely been investigated so far.

Among others, the electric pendulum is a powerful analytical tool for the indication of electrical events that are co-variant with major geophysical phenomena. Preliminary recordings seem to indicate that an electrical disturbance can be noted not only during but also preceding earthquakes, volcanic eruptions and hurricanes. It is submitted as a working hypothesis that changes of geo-electric currents may precede the major mechanical stress-relief that appears afterwards in the form of an earthquake. The electric pendulum under the proper conditions may be capable of sensing such changes in the electronmagnetic conditions ahead of time. Data found here occasionally offer a fascinating possibility although they are not conclusive at this time since such work can be done only by around-the-clock observations and requires also other refinements.

The electrical phenomena apparently associated with major perturbations are of such a nature that further work seems to be indicated. This includes also man-made events such as nuclear detonations which are known to cause electric disturbances. These, together with other sensors, offer the fascinating possibility of an additional sensing means of high sensitivity, specificity and resolving power together with an increased signal-to-noise ratio.

I thank the Rev. Fr. Daniel Linehan, S.J., director of Weston Observatory, who, after inspection of my instruments and recordings, co-ordinated their comparison with his records for the elimination of seismic and magnetic disturbances from the observations shown.

I also thank Prof. Edwin B. Wilson for his advice and Prof. Hans Thirring, who put on record the original form of these findings before the Austrian Academy of Sciences.

REACTION BETWEEN PORTLAND CEMENT CLINKER AND WATER

By A. K. CHATTERJI and T. C. PHATAK
Central Building Research Institute, Roorkee, India

IT has been recently suggested that the reaction between Portland cement clinker minerals and water (hydraulic action of cement) may be an 'acceptor'-type semiconductor surface reaction[1]. To verify this suggestion one has to find if individual clinker minerals are semiconductors and, if so, their type of semiconductivity. Further, and, this is more important, it is necessary to see if the electrical conductivity of individual clinker mineral is related with its hydraulic action. This is to be expected, if the foregoing suggestion is correct, as the electrons responsible for electrical conduction are also the electrons which take part in this type of reaction.

As individual minerals in the clinker (di- and tri-calcium silicate, tri-calcium aluminate, tetracalcium alumino ferrite) suitable for semiconductor studies were not available, experiments were carried out with ordinary Portland cement clinker, which consists of a mixture of the aforementioned minerals and of some lime (removed later) and MgO.

The clinker was powdered and the fraction passing B.S. 300 mesh sieve was made free of lime by repeated washing with absolute alcohol, and the material thus obtained was used in these experiments. Within the limitation imposed by the material, the results indicate that the amount of hydration of Portland cement clinker in a given time and its electrical conductivity change in opposite direction (anti-parallel). This means that the hydraulic action of Portland cement clinker is a semiconductor surface reaction. Since the type of semiconductivity of clinker is unknown, it is not possible at this stage to specify the 'type' of the reaction ('acceptor' or 'donor').

To examine the semiconducting property of the clinker, variation of electrical conductivity with temperature was the only measurement which could be undertaken. To correlate electrical conductivity of clinker with hydration, it is necessary to change the electrical conductivity of the clinker, and this was effected (1) by heating the clinker at 1,000° C for 4 h and (2) by heating the clinker in a similar manner after thoroughly mixing it with 1 per cent (by weight of clinker) of each of these oxides individually: (*a*) Cr_2O_3, (*b*) ZnO, (*c*) MoO (possibly so, the material was actually heated with ammonium molybdate), (*d*) MnO_2, (*e*) CoO and (*f*) NiO. As no sintering was observed, the surface area was taken to have remained unchanged. Both fired and unfired materials were made into tablets under a total pressure of 3,500 lb. as done previously[1]. Electrical resistance of the tablets was measured at room temperature, without a conducting layer. The variation of electrical conductivity of the tablets with temperature (rising by steps of 25° C up to 950° C) was also measured in the manner described earlier[1].

For hydration, fresh tablets, made from both fired and unfired materials, after measuring their resistances at ordinary temperature and their weights, were put for hydration at ordinary temperature over water in a moist atmosphere (vapour hydration) in a closed container for 3 days. The tablets were then dried at 110° C for 24 h and weighed and their increase in weight found. These were then allowed to hydrate for a further period of 7 days by immersing them in de-ionized distilled water. Three tablets, of the same treatment, were placed in 50 c.c. water at ordinary temperature. These were dried,

and gains in weight noted. Gain in weight per gramme of clinker was calculated for vapour hydration and for both vapour and water hydration combined (total hydration). The gains in weight were corrected for the weight of calcium hydroxide formed during the hydration of dicalcium and tricalcium silicates on the basis of the equations given by Hansen[2]. This correction covers about 75 per cent of the clinker. Correction for reaction products other than the cementitious hydrates for the rest of the material was neglected. Loss of lime during water hydration was also neglected.

When logarithms of electrical conductivities of the treated and untreated clinker at different temperatures are plotted against $1/T$ (T in deg. K), the conductivity is seen to fall up to 200° C and then rises continuously except for those heated without any addition and heated with ZnO and MoO. In these, a slight rise in conductivity up to about 50° C is observed, which then falls to a minimum at about 200° C and then rises continuously with temperature. Variation of electrical conductivity with temperature indicates that the material may be behaving as a semiconductor, and, since these measurements do not yield any information regarding the type of semiconductivity of these materials, the curves are not produced.

Electrical conductivity at ordinary temperature of the treated and untreated cement clinker and the gain in weight on hydration through vapour hydration and total hydration, corrected and uncorrected, are given in Table 1. Results of hydration of 23 tablets are given; one, with MnO_2 added, was broken during experiment. There is no relationship between the (corrected) gain in weight by vapour hydration and electrical conductivity. This is apparently due to all minerals not taking part in hydration during this part of the hydration while conductivity takes into consideration the entire mass. However, when the corrected gain in weight after total hydration is plotted against electrical conductivity some of the points fall along one straight line and a few along another with a different slope (Fig. 1). Such behaviour is quite possible. There is considerable dispersion of points also. This is expected when one takes into consideration the state of inhomogeneity of the material together with the fact that the change in the electrical conductivity produced in individual minerals on treatment cannot be uniform.

The nature of the curves indicates that the amount of hydration of Portland cement clinker, in a given time, is related to its electrical conductivity in an anti-parallel way. This means that the reaction between Portland cement clinker and water (hydraulic action of cement) is a semiconductor surface reaction. It may either be '*n*' type reaction on '*p*' type semiconductor or '*p*' type reaction on '*n*' type semiconductor. Taking into consideration the arguments given earlier[1], and also the similarity in the hydration of lime and cement, and, as the reaction between lime and water may be an '*n*' type reaction[3], it appears that the hydraulic action of Portland cement clinker is '*n*' type reaction on '*p*' type semiconductor, that is, the clinker material is behaving as a '*p*' type semiconductor.

ALPHA-RADIOACTIVITY OF PLANKTON

By R. D. CHERRY

Department of Physics, University of Cape Town, Rondebosch, South Africa

In recent years considerable attention has been directed to the problem of radioactive contamination of the marine environment, and several measurements of artificially produced radioactive isotopes in plankton have been reported (for example, Osterberg *et al.*[1]). By comparison, the naturally occurring radioactivity of plankton has received scant attention. The activity due to the mixed β–γ emitter potassium-40 has been the subject of some discussion, and Rama *et al.*[4] have made brief mention of lead-210. The α-activity appears to have been almost totally neglected since the early work of Evans *et al.*[2] and Føyn *et al.*[3] on the radium contents. A recent report by Marsden[5], which indicated high α-activities and interesting problems associated with possible disequilibria in the radioactive series, has revived interest in this problem, and as a result of this report a programme for investigating the α-radioactivity of plankton has been started here.

So far, only 'total' α-counting plus thorium-series 'pairs' measurements have been made. The experimental set-up is based on that of Turner *et al.*[6]. This consists of a sealed phosphor-sample system of high sensitivity and simplicity. This type of system has been used with success in several investigations[7] of samples from the natural radiation environment, and it provides: (*a*) a measurement of the total α-activity; (*b*) an estimate of the percentage of this activity which is due to the thorium series. The particular set-up used in these experiments utilized Levy–West *G* 86 ZnS(Ag) as phosphor, E.M.I. 9530 *B* photomultiplier tubes and low cathode-to-first dynode resistor values[8]. This combination resulted in the low background value of less than 1 count/h for a 4½-in. diameter phosphor. It is perhaps worth mentioning that, on such a phosphor, one sample count/h above background will correspond to less than 0·1 pc./g α-activity in the sample, or to a thorium content of less than 0·1 p.p.m. in a hypothetical sample containing only the thorium series in equilibrium.

Sample preparation is very simple. The plankton is dried at 105° C, finely ground and then packed on the Scotch tape–'Perspex' ring–ZnS phosphor system as described by Turner *et al.*[6]. The sample is sealed on top with additional tape. No emanation problems arise provided that the sample is left for 2–3 weeks after preparation in order to allow radon to regain equilibrium. Ashing of the sample was avoided in order to prevent loss of the volatile element polonium; in any event, the extra concentration provided by ashing was not required.

Results have been calculated using the usual 'thick-source' α-counting formula (for example, Finney and Evans[9], Turner *et al.*[6], Cherry[10]). This requires a knowledge of the range of the α-particle in the sample material, and the formula which assumes proportionality to $Z^{2/3}$ has been used in the present work. The range problem has been discussed previously[11] by me; here it will suffice to mention that lack of consistent experimental knowledge concerning α-particle ranges in solids results in an inherent uncertainty in the absolute values of results obtained by thick-source α-counting techniques. Should some recent α-particle range data (for example, those of Kamke and Kramer[12]) be substantiated, then all the activity values in the present article might have to be lowered by about 25 per cent. $Z^{2/3}$ has, of course, to be calculated on the usual 'atomic fraction' basis. For dry zooplankton a composition of major elements with an atomic ratio of 212 : 176 : 106 : 16 : 1 for oxygen : hydrogen : carbon : nitrogen : phosphorus has been assumed. These values give $Z^{2/3} = 2{\cdot}81$. The phytoplankton samples measured are mostly diatomaceous, and atomic ratios of 191 : 158 : 95 : 38 : 15 : 4 : 2 : 1 for oxygen : hydrogen : carbon : silicon : nitrogen : calcium : iron : phosphorus have been used to calculate $Z^{2/3} = 3{\cdot}11$. The compositions used are based on data given by Sverdrup *et al.*[13], and might be subject to some error. Fortunately, however, $Z^{2/3}$ is a slowly varying function, and the resulting error in $Z^{2/3}$ is likely to be unimportant at this stage; the 10 per cent difference between the zoo- and phyto-plankton values of $Z^{2/3}$ is probably indicative of the order of magnitude of the most serious discrepancy which is likely to arise from this source.

The five sections of Table 1 represent different groups of samples. Section 1 comprises samples consisting predominantly of zooplankton which were collected at various dates from 1899 until early in 1962. With the exception of the last sample listed (No. 6) all these specimens were obtained from the collections of the South African Museum, Cape Town, and were supplied by Mr. J. G. Grindley of the Museum. Sample No. 6 and those in Sections II and III were collected by the University of Cape Town research vessel *John D. Gilchrist*. The Section II samples are also zooplankton; they are being collected at approximately monthly intervals from the 'Slangkop Station'. Section III comprises phytoplankton data; these samples are collected at the same time as the zooplankton specimens of Section II, but with a different net. Finally, Section IV gives data for phytoplankton collected either during the 1958 International Geophysical Year cruises of the S.A.S. *Natal* or during the 1962 International Indian Ocean Expedition cruises of the same vessel. The *John D. Gilchrist* and the S.A.S. *Natal* samples were provided by Messrs. J. Stone, F. J. R. Taylor and P. Zoutendyk of the Council of Scientific and Industrial Research Oceanographic Research Unit at the University of Cape Town. The solitary sample in Section V represents the only pre-war phytoplankton specimen so far obtainable. It came from the same source as the samples of Section I.

Results are also given in Table 1. Total α-activities are quoted in picocuries per gram (that is, μμc./g). Relative standard deviations due to counting statistics are in all cases 5 per cent or less, and are generally of the order of 3 per cent. The most serious errors will probably arise from the α-range problem already discussed; as previously indicated, it is possible that this could result in all the values quoted being too high by as much as 25 per cent. Percentage contributions to the total α-activity by the activity due to the thorium series alone are also quoted. These are obtained by counting the 'pairs'[6,10] due to the successive α-decays of the isotopes emanation-220 and polonium-216. Since these 'pairs' rates are, typically, lower by a factor of about 40 or 50 than the total count-rates, the errors due to counting statistics are appreciably larger than for the total α-activities. A standard deviation of about 20 per cent would be average. A further uncertainty is caused by the fact that it is not known for certain whether the thorium series activity is in complete equilibrium from the isotope thorium-232 downwards. This has been assumed to be the case in calculating the percentage quoted; should either radium-228 or thorium-228 prove to be the true parent of the 'pairs' activity, the quoted values would have to be lowered by a factor of about 0·9.

The data in Table 1 require to be supplemented by some comments about the time-dependence of the counting rates of samples. All the data quoted in the table were obtained from counts during the period December 1963–March 1964. Samples in Sections II and III were, if possible, counted about one month after collection (and about three weeks after drying and mounting); in some cases, however, the interval between collection and counting was as great as ten weeks. In addition to the results quoted, additional counts, separated in time by varying intervals, have been made on several of the samples listed. The project has not been under way for a sufficiently long time for definite conclusions to be drawn, but the results so far obtained can be summarized thus:

(1) None of the phytoplankton samples has exhibited any time-dependence in the α-activity within the limits of statistical error.

(2) Several of the zooplankton samples in Section II, which are all recent samples, have shown slight decreases (of up to 25 per cent) when re-counted two to three months after the original count.

(3) With the exception of sample No. 6, which will be discussed separately, none of the zooplankton samples in Section I has exhibited any time-dependence over a period of about six months.

(4) None of the samples has exhibited a rise in α-activity with time, apart, of course, from the small rise sometimes observed due to radon build-up if the samples are counted too soon (within two or three weeks of drying).

(5) The pairs rates statistics are at present too poor to permit of any serious conclusions on variations with time. It is, nevertheless, worth mentioning that, within the wide

limits of statistical error, no time-dependence in the pairs rate has been observed for any of the samples.

(6) Sample 6 (zooplankton) is worthy of special mention since its α-activity has been followed intermittently over a period of two years. A month after preparation its α-activity was as high as 19 pc./g. This declined steadily, until eighteen months later (in September 1963) the level was down to 2·1 pc./g. In January 1964, the value was as given in Table 1 (2·1 pc./g) indicating no significant change during the intervening four-month period. The rate of fall-off between March 1962 and September 1963 as measured by a set of six readings fitted an exponential decay with a half-life of about 140 days. It is difficult to see how this can be ascribed to anything other than the presence of the well-known α-emitter polonium-210, which has a half-life of 138 days. The experimental facts support the hypothesis that the sample initially contained about 17 pc./g of unsupported polonium-210 plus a 'long-lived' (half-life $\geqslant$ 2 years) α-activity of about 2 pc./g. No statistically significant variation in the pairs rate was observed between March 1962 and January 1964; the percentage contribution of the thorium-series activity has thus risen from about 2 per cent to the present value of 22 per cent.

Total α-activity of plankton. The results presented indicate that fresh plankton contains in general (if the samples tested are typical) upwards of 4 pc. α-activity/g dried sample. The means for the 'routine' samples of Sections II and III are in fact 6·7 pc./g for zooplankton and 5·1 pc./g for phytoplankton. It is clear, moreover, that for the zooplankton some of the initial activity is often of 'short-lived' ($\leqslant$ 2 years) duration, and that this short-lived activity can, as in the case of sample 6 and possibly *GIL* 526 as well, contribute an activity considerably in excess of the 'basic' 4 pc./g. No such short-lived activity has been observed in phytoplankton samples; but this may merely be a reflexion on the relatively small number of samples thus far tested. Some phytoplankton samples, on the other hand, do show almost sensationally high values of α-activity, and this high level seems to persist for a time of five years or more—see the International Geophysical Year samples in Section IV.

It is of interest to consider the foregoing comments in relation to the radiation dosage received by the living planktonic organism. The range of a typical α-particle in living plankton will be about 10–15μ. If we consider a plankton specimen with dimensions very much larger than this figure (true for most zooplankton), then to a good approximation all the α-particles emitted by the specimen will be absorbed in the specimen itself. This will, of course, not be true if the α-particles are distributed on the surface alone, but even in this event only a small correction factor of the order of 2 or 3 will be involved. Suppose that the plankton contains 4 pc. α-activity/g dried material. The concentration factor between 'wet' and dry plankton will be about 16 (ref. 13), thus giving us a concentration of about 0·25 pc. α-activity/g living plankton. If we next assume that the average α-particle energy is 5 MeV, then we find that the radiation dosage to the organism from its own inherent α-activity is about (2·6) (10^{-3}) millirads per hour or about 23 millirads per year. Furthermore, α-radiation is generally considered to have a relatively high biological efficiency ; if we use the usually quoted relative biological efficiency (R.B.E.) of 10 for naturally occurring alphas, then we end up with a dosage of about 230 millirem per year. Folsom and Harley[14] quote radiation doses in millirads per year in "eleven radiological domains". They estimate the radiation dose to a micro-organism near the sea-surface to be about 39 millirads per year from external sources ; since most of this is due to minimum ionization radiation, this can be considered to be equivalent to about 39 millirem per year. It is thus apparent that the radiation dose to our plankton specimens will be derived very largely (80 per cent or more) from internal α-radioactivity. Contrast this with the situation in human body tissue: Eisenbud[15] quotes tissue dose rates of between 120 and 140 millirem per year to various body tissues, and the contribution of internal α-activity to these figures varies between 4 and 15 per cent. Furthermore, it should be emphasized that the 'basic' figure of 4 pc./g is definitely at the lower limits of the α-activity concentration in fresh plankton so far as the present samples are concerned. Consider the phytoplankton sample *NGY* 16, with about 96 pc. α-activity/g dried plankton. This sample has been identified by Mr. F. J. R. Taylor as a mixed bloom with the relatively large diatom *Rhizosolenia hyalina* Ostenfeld predominating. The diatoms in this sample have typical dimensions of about 300μ long and 35μ diam., and with typical α-ranges of about 10–15μ it is reasonable to assume that something like half the α-energy is internally absorbed. A simple calculation then shows that the α-radiation will deliver a dose of about 2·8 rems per year to the diatom. This is exceptionally high, and bears comparison with the large (external) radiation doses received by the human population living on the thorium-bearing sands in Kerala, India[15]. Most phytoplankton are, of course, smaller and will thus tend to 'lose' more of their α-particle energy to the surrounding sea. What has been said will nevertheless suffice to indicate that at least some plankton must carry an abnormally high internal radiation burden of natural origin. It is perhaps relevant to compare the dried plankton figure of 4 pc./g with the reported α-activities of foodstuffs. Thus Turner *et al.*[22] quote values of up to 0·005 pc./g for meats. 0·04 pc./g for fish and 0·6 pc./g for cereals. Only in exceptional cases (for example, Brazil nuts, 17 pc./g) do the activities rise above the dried plankton figure. Another interesting 'high' α-activity is that reported by Hill[16] in lamb's kidney, namely, about 2 pc./g wet tissue.

α-Emitting elements in plankton. The results presented here involve no chemistry or α-spectroscopy, and do not therefore permit definite identification of the nuclei responsible for the α-particle emission. However, the use of the 'pairs' technique, the measurements of time-dependence of the α-activity and the fact that a few measurements have been made on relatively old samples do allow of a few reasonable deductions. We shall consider the figure of 4 pc./g dried material to be 'basic' for fresh plankton, as in the previous section. It must, however, be borne in mind that this figure is probably on the low side, and is certainly subject to very wide variation. We shall discuss elemental abundances as follows:

(1) *Polonium.* As already suggested here, there is strong evidence that the 138-day isotope polonium-210 can in some cases be responsible for a substantial portion of the initial activity of plankton specimens. This is not surprising: polonium-210 is, after all, a 'natural fall-out' product, and Hill[16,17] and others have measured this nuclide in grass, various tissues and other environmental samples. It is interesting that the measurements on sample 6 and on some of those in Section II seem to indicate that the polonium is, in part at least, unsupported by its parent lead-210. Lead-210 has a 22-year half-life, and is generally considered to be an important contributor to natural fall-out. Since the residence time of lead-210 in the atmosphere is estimated to be of the order of a few weeks[18,23] it is unlikely that polonium-210 will accompany fall-out lead-210 in amounts approaching equilibrium activity. In fact, Burton and Stewart[18] found an average lead-210 to polonium-210 activity ratio of 10 in rain-water samples. After fall-out lead-210 will, of course, decay to polonium-210, and one would therefore expect an exponential increase of α-activity with the 138-day polonium-210 time constant if the plankton samples at the time of collection contained appreciable amounts of fresh, unsupported, lead-210 fall-out nuclei. No such increase has been observed in any of our samples, although increases in activity with time have been reported by

Marsden[5]. Factors such as the residence times of polonium and lead in the upper layers of the ocean must also be taken into account; but it is possible that the results quoted here might be construed as indicating preferential intake of polonium-210 by planktonic organisms. Obviously many more results are required before the situation can be clarified. It is perhaps worth directing attention to the fact that polonium-210 radioactivity appears to be assuming increasing biological importance; thus Hill[17] states that "in bone and many of the soft tissues of normal unexposed human subjects, polonium-210 appears to be responsible for a large part of the total natural activity". He quotes polonium-210 concentrations in various human tissues which are typically of the order of 4×10^{-3} pc./g of wet tissue, and in another paper[16] finds that the α-activity of 2 pc./g in lamb's kidney previously quoted is due almost entirely to polonium-210. If we assume (see Sections I and II, Table 1) that about half the 'basic' 4 pc./g in dry zooplankton is due to polonium-210, then a typical value would appear to be of the order of 125×10^{-3} pc./g 'wet' plankton—considerably larger than for human tissue. The 'concentration factor' for polonium-210 from sea-water to zooplankton is also of interest. Rama *et al.*[4] quote a lead-210 concentration in surface waters of about 0·1 disintegrations/min/l., or about 5×10^{-5} pc./g. Picciotto[19] quotes a radium-226 concentration in sea-water of about 9×10^{-5} pc./g. Both these nuclei are parents of polonium-210, and it seems reasonable to assume that the polonium-210 content of sea-water will not be more than 10^{-4} pc./g. Comparing this with our figure of 250×10^{-3} pc./g in wet plankton implies a concentration factor of more than 2,500; even this figure is likely to be a conservative estimate.

(2) *Thorium series isotopes.* The thorium series comes into equilibrium rapidly after the 1·9 year nuclide thorium-228, and it is plain that the thorium series activity in the plankton must be supported by either thorium-228 or its precursors, 6·7 year radium-228 and/or $1 \cdot 4 \times 10^{10}$ year thorium-232. The fact that the 1899 and 1904 samples still show considerable thorium-series activity indicates that the long-lived thorium-232 is probably at least partially responsible. For the purposes of the present discussion it seems safe to assume that the thorium series will contribute, typically, upwards of 0·4 pc./g of dried plankton to the α-activity. This is equivalent to about 0·025 pc/g of wet plankton. Calculations based on Picciotto's[19] results (which give $1 \cdot 2 \times 10^{-7}$ d.p.s./ml. for thorium-228 in sea-water) give a thorium series contribution to the sea-water α-activity of about 2×10^{-5} pc./g. This gives a concentration factor of about 1,250, and again this is likely to be a conservative estimate.

Rama *et al.*[4] have suggested in their paper on lead-210 in the ocean that "the marine biosphere is responsible for the conveyance of lead from surface to deeper waters". The results just discussed indicate that the same may be true for the nuclides at the head of the thorium series, although, of course, the ferric hydroxide precipitation mechanism suggested by Pettersson[20] to account for the deficiency in sea-water of ionium (that is, thorium-230, a uranium series nuclide) might also operate.

(3) *Uranium and radium.* After allowing for short-lived activity and for the thorium series contributions of (1) and (2) we are left with upwards of 1–2 pc./g of α-activity unaccounted for. This must presumably be due to the uranium-series, and is probably supported by 1,620-year radium-226 and/or one or both of its uranium parents. 1·6 pc./g dry plankton would give about 0·1 pc./g wet plankton; Picciotto's sea-water data give us a concentration of just under 0·002 pc./g sea-water for the uranium series contributions, implying a concentration factor of the order of 50. It is interesting to note that the pre-war measurements of Evans *et al.*[2] on a single zooplankton sample gave a concentration factor of about 100 for radium, while those of Føyn *et al.*[3] on a phytoplankton sample gave a factor of 1,000 for the same element. The results we have quoted do not enable us to distinguish between the uranium and the radium contributions, but the approximate agreement with the sample of Evans *et al.*[2] is interesting. It would, of course, be easy to match the Føyn *et al.*[3] sample with one of the more active phytoplankton samples from Section III of Table 1. It is perhaps worth stating that Evans *et al.*[2] quoted a content of $0 \cdot 04 \times 10^{-12}$ g radium/g dry zooplankton, while Føyn *et al.*[3] obtained 2×10^{-12} g radium/g dry phytoplankton. If we assume radium-226 to be the head of the uranium series contribution, and assume radioactive equilibrium from there downwards, then 1 pc./g of radium-supported α-activity corresponds to $0 \cdot 2 \times 10^{-12}$ g radium/g dry plankton.

Locality of sample collection. Since relatively few samples have been measured in this preliminary survey, very little emphasis has been placed on the question of sample locality. For record purposes, we can divide the collection sites as follows:

(*a*) All the samples in Sections II and III of the table were obtained at the 'Slangkop Station', situated about 7 miles offshore west of the Cape Peninsula.

(*b*) Samples No. 3, 4, 6 and 'Robben Island' were also obtained in the vicinity of the Cape Peninsula.

(*c*) Sample No. 5 was obtained from Lambert's Bay, about 120 miles north of Cape Town.

(*d*) Sample No. 1 was from Mossel Bay, about 250 miles east of Cape Town.

(*e*) Sample No. 2 and the International Geophysical Year and Indian Ocean Expedition samples in Section IV were obtained off the south-east coast of South Africa between Port Elizabeth and Durban. *NGY* 16 and *NIOE* 7 are the only two of these samples which were obtained at points clearly off the continental shelf. The International Geophysical Year samples in Section IV have been described in detail by Zoutendyk[21].

Table 1. α-ACTIVITIES OF DRIED PLANKTON SAMPLES

Section and type	Sample No.	Date of collection	Total α-activity in pc./g dried material	Thorium series contribution (%)
Section I Zooplankton	1	1899	1·8	20
	2	1904	3·6	28
	3	1947	2·5	32
	4	1950	2·0	46
	5	1957	2·5	14
	6	1962	2·1	22
Section II Zooplankton	*GIL* 526	2/10/63	12·0	17
	GIL 527	29/10/63	3·9	13
	GIL 528	26/11/63	6·7	22
	GIL 537	18/12/63	5·3	31
	GIL 536	29/1/64	5·7	14
Section III Phytoplankton	*GIL* 526	2/10/63	7·7	20
	GIL 527	29/10/63	3·4	34
	GIL 528	26/11/63	3·6	17
	GIL 537	18/12/63	4·4	16
	GIL 536	29/1/64	6·3	29
Section IV Phytoplankton	*NGY* 8	2/3/58	18·3	35
	NGY 16	3/3/58	95·5	8
	NGY 25	18/5/58	16·5	14
	NGY 29	19/5/58	28·6	8
	NGY 33	21/5/58	31·4	13
	NGY 38	22/5/58	5·5	29
	NGY 42	24/5/58	6·3	26
	NIOE 7	8/4/62	4·0	33
	NIOE 18	12/4/62	6·5	36
Section V Phytoplankton	'Robben Island'	7/7/35	3·8	24

It is tempting to associate the higher activities of the Section IV samples with the warmer waters of the eastern side of the sub-continent, but this is not justified on the basis of the data presented here. Additional information is obviously required.

I thank Sir Ernest Marsden for directing my attention to this problem, and Prof. J. H. Day and Messrs. J. G. Grindley, J. Stone, F. J. R. Taylor and P. Zoutendyk for the provision of samples and for their advice. I also thank Mr. L. A. Pasvol and Mr. L. V. Shannon for preparing some of the samples for counting and the Council of Scientific and Industrial Research Oceanographic Research Unit at the University of Cape Town for financial assistance.

INCONSTANCY OF RENAL CLEARANCE VALUES WITH CHANGING PLASMA CONCENTRATIONS

By DR. REX B. CONN, JUN., ALEX J. SABO, DALE LANDES and JAMES Y. L. HO

Department of Pathology and Department of Theoretical and Applied Mechanics, West Virginia University, Morgantown, West Virginia, U.S.A.

ONE of the basic tenets in the concept of renal clearance is that clearance (the calculated volume of plasma which is cleared of a substance per unit time) is independent of plasma concentration, provided that tubular saturation does not occur. In experiments which utilized a fraction collector to obtain frequent urine specimens we have found that clearance of *o*-iodohippurate sodium ('Hippuran') does not remain constant following a single intravenous injection, but on the contrary it declines as the plasma 'Hippuran' concentration declines[1]. Since this finding is in gross conflict with the constant clearance concept which has proved so valuable over the past 30 years, we have sought to develop a mathematical model of the kidney which will reconcile our findings with those of other investigators. At the same time we have attempted to provide explanations for two observations regarding renal clearance which we believe to be thus far inadequately explained. The first is the observation that extraction ratios of substances excreted by tubular secretion rarely exceed 90 per cent. This has been attributed to the passage of 10 per cent of the renal blood through non-excretory renal tissue[2]. Such profligacy in the distribution of myocardial work appears unlikely. The second observation is that of Mitchie and Mitchie[3], who found that following rapid attainment of a constant *p*-aminohippurate plasma concentration about 20 min are required before its clearance becomes constant although it appears in the urine within a much shorter time.

Published data of other investigators indicated that clearance of *p*-aminohippurate and of 'Hippuran' may change with changing plasma concentrations; however, the lack of urinary excretory data permitted these investigators an alternative explanation for their findings. The overall excretion of any substance should follow first order kinetics if clearance is calculated in the usual way.

$$C = \frac{UV}{P}$$

where C, clearance; U, urine concentration; V, volume of urine excreted per unit time; P, plasma concentration. Because of the technical difficulties involved in measuring clearance by the sustaining infusion technique many attempts have been made to determine renal clearance by following the disappearance of exogeneous substances from the plasma after a single intravenous injection. Although these attempts have not been entirely successful in their original purpose, the plasma disappearance curves indicated that something more than simple first order kinetics was involved.

With first order kinetics, assuming extra-renal losses are insignificant and clearance remains constant, the plot of log P versus time should yield a straight line since UV in the equation for clearance can be equated to $V_p\left(-\frac{\mathrm{d}P}{\mathrm{d}T}\right)$, where V_p is the volume of distribution of the substance, and $\frac{\mathrm{d}P}{\mathrm{d}T}$ represents change in plasma concentration with time.

$$C = \frac{V_p\left(-\frac{\mathrm{d}P}{\mathrm{d}T}\right)}{P}$$

$$\int \frac{C}{V_p} \mathrm{d}T = -\int \frac{\mathrm{d}P}{P} + C_1$$

$$\frac{C}{V_p} T = -\ln P + C_1$$

The plot of log P versus T will give a straight line of slope $-2{\cdot}303\frac{C}{V_p}$. Such disappearance curves have been obtained for mannitol[4-6]. Deviations from this equation for inulin have been attributed to a barrier to free diffusion between intravascular and extravascular spaces[7]. Plasma disappearance curves of *p*-aminohippurate[8] and 'Hippuran'[9,10] deviate markedly from this equation, however, and such deviations have been ascribed to a distribution throughout a two-compartment system[8]. Another explanation for these findings is that clearances of *p*-aminohippurate and 'Hippuran' do not conform to the foregoing equations because clearance changes as the plasma concentration declines. More direct evidence for the latter may also be found[11,12].

The requirements for our mathematical model of the kidney may therefore be described as follows:

(1) If plasma concentration remains constant, clearance is independent of plasma concentration for all concentrations (if tubular saturation does not occur) and for all substances whether excreted by glomerular filtration or tubular secretion.

(2) For substances excreted by glomerular filtration alone clearance remains constant even with a varying plasma concentration.

(3) For substances excreted by glomerular filtration alone the plasma concentration will decline logarithmically with time following a single intravenous injection (assuming extra-renal losses are insignificant).

(4) For substances excreted by tubular secretion, clearance will not remain constant if the plasma concentration varies.

(5) For substances excreted by tubular secretion, the plasma concentration will not exhibit a logarithmic decline following a single intravenous injection (assuming extra-renal losses are insignificant).

(6) Experimentally determined extraction ratios must be explained by some mechanism other than passage of renal blood through non-excretory renal tissue.

(7) It must not conflict with the experimental finding that following almost immediate attainment of a constant plasma *p*-aminohippurate concentration clearance will attain a constant value later than the material appears in the urine.

Previous discussions of the kinetics of renal tubular secretion have apparently overlooked an important anatomical fact. Substances which are secreted by the tubules must pass first from the capillaries into the renal interstitial fluid from which the tubule cells may then remove them for transport into the lumina of the tubules. Thus the tubule cells cannot act directly on the material within the capillaries. If a substance were to be completely removed from the capillary plasma in one passage through the excretory tissue of the kidney (the concept at present held for substances with high extraction ratios such as *p*-aminohippurate), the requirements of the diffusion process are such that the tubular excretory processes must maintain the interstitial fluid concentration at virtually zero concentration. The latter appears unlikely. It is probable that active tubular secretion can reduce the interstitial fluid concentration of certain substances to a low, but appreciable, level. This would result, therefore, in incomplete extraction of all substances passing through the renal excretory tissue and would provide an acceptable alternative to our present explanation for maximum extraction ratios of 90 per cent. If this explanation proves correct it will require certain changes in our concept of effective renal plasma flow. Probably all substances which are freely diffusible across the capillary endothelium attain concentration equilibrium between interstitial fluid and capillary plasma before the latter leaves the kidney.

In a model of the kidney six processes which are involved in renal excretion of any substance must be considered: R_1, the rate at which it enters the kidney via the renal arteries; R_2, the rate at which it leaves the kidney via the renal veins; R_3, the rate at which it is filtered by the glomerulus; R_4, the rate at which it diffuses through the capillary endothelium; R_5, the rate at which it is transported from the interstitial fluid into the lumen of the tubule; R_6, the rate at which it is excreted into the ureters. The dimensions of all these rates are $\left(\frac{\text{mass}}{\text{time}}\right)$. These processes are depicted in Fig. 1.

General equations. Let K_1 be the total renal plasma flow (which remains constant under experimental conditions). P is plasma concentration.

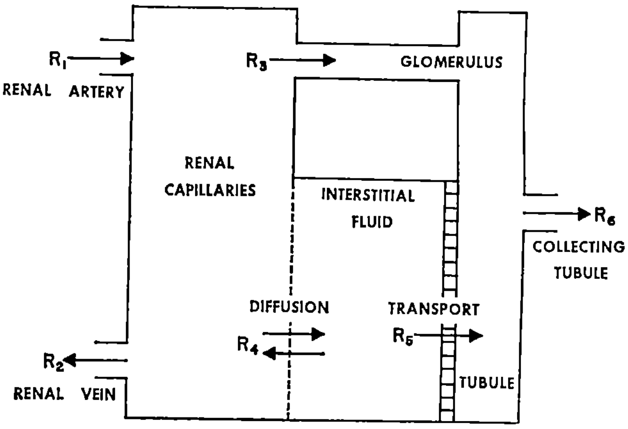

Fig. 1

$$R_1 = K_1P \qquad (1)$$

Let N equal the concentration in renal interstitial fluid. Assuming the concentration in efferent renal plasma is the same as that in the renal interstitial fluid and disregarding that small fraction of renal plasma water which is excreted as urine:

$$R_2 = K_1N \qquad (2)$$

Let K_3 be the glomerular filtration rate (which remains constant under experimental conditions). The rate at which any filtrable substance is removed by glomerular filtration is:

$$R_3 = K_3P \qquad (3)$$

Let Q be the amount of material removed from the plasma at time T through both glomerular filtration and tubular secretion:

$$\frac{dQ}{dT} = R_1 - R_2 = R_3 + R_4 \qquad (4)$$

R_5 is the rate at which a substance is secreted into the tubules from the renal interstitial fluid. Since this is an enzymatic reaction its rate at low substrate concentration should be proportional to the substrate concentration which is the concentration in the renal interstitial fluid:

$$R_5 = K_5N \qquad (5)$$

It is recognized that concentration may not be the same throughout the interstitial fluid, and R_5 and N can represent the mean reaction rate and mean concentration respectively. Let V_n be the volume of the renal interstitial fluid space. The change in interstitial fluid concentration may be defined by the following equation:

$$V_n\frac{dN}{dT} = R_4 - R_5 \qquad (6)$$

Let M be the amount of material excreted into the ureters in time T through both glomerular filtration and tubular secretion.

$$\frac{dM}{dT} = R_3 + R_5 = R_6 \qquad (7)$$

Since clearance is the rate of excretion divided by the plasma concentration:

$$\text{clearance} = \frac{UV}{P} = \frac{\frac{dM}{dT}}{P} \qquad (8)$$

From equations (3), (5), (7) and (8):

$$\text{clearance} = \frac{\frac{\mathrm{d}M}{\mathrm{d}T}}{P} = K_3 + \frac{N}{P}K_5 \tag{9}$$

These equations must fit all situations outlined above in the requirements for a model of the kidney. In the following sections these various situations will be considered.

Clearance values for glomerular filtration without tubular secretion. If there is no tubular secretion $R_5 = 0$ and from equation (9):

$$\frac{\frac{\mathrm{d}M}{\mathrm{d}T}}{P} = K_3$$

The rate of excretion will be proportional to plasma concentration and clearance will remain unchanged at all values for P whether it is constant or changing.

Clearance values for excretion by both glomerular filtration and tubular secretion. If excretion occurs by both glomerular filtration and tubular secretion $R_5 \neq 0$ and:

$$\text{clearance} = \frac{\frac{\mathrm{d}M}{\mathrm{d}T}}{P} = K_3 + \frac{N}{P}K_5$$

The following equations will show in the model that if plasma concentration remains constant throughout the experimental period clearance will be the same for all plasma concentrations. If plasma concentration varies, however, clearance will not remain constant.

From equation (4):

$$R_4 = R_1 - R_2 - R_3 \tag{10}$$

From equations (6) and (10):

$$V_n\frac{\mathrm{d}N}{\mathrm{d}T} = R_1 - R_2 - R_3 - R_5 \tag{11}$$

From equations (1), (2), (3), (5) and (11):

$$V_n\frac{\mathrm{d}N}{\mathrm{d}T} = K_1P - K_1N - K_3P - K_5N \tag{12}$$

$$V_n\frac{\mathrm{d}N}{\mathrm{d}T} = (K_1 - K_3)P - (K_1 + K_5)N \tag{13}$$

$$N = \frac{(K_1 - K_3)P - V_n\frac{\mathrm{d}N}{\mathrm{d}T}}{K_1 + K_5} \tag{14}$$

$$\text{clearance} = \frac{\frac{\mathrm{d}M}{\mathrm{d}T}}{P} = K_3 + K_5\left[\frac{(K_1 - K_3)}{(K_1 + K_5)} - \frac{V_n\frac{\mathrm{d}N}{\mathrm{d}T}}{P(K_1 + K_5)}\right] \tag{15}$$

If plasma concentration is constant throughout the experimental period the interstitial fluid concentration will attain an equilibrium condition in which it also is constant and $\frac{\mathrm{d}N}{\mathrm{d}T} = 0$. In these circumstances:

$$\text{clearance} = K_3 + K_5\left[\frac{K_1 - K_3}{K_1 + K_5}\right] \tag{16}$$

Thus clearance is independent of plasma concentration if the latter remains constant and $\frac{\mathrm{d}N}{\mathrm{d}T} = 0$. If P changes, however, N will vary also and $\frac{\mathrm{d}N}{\mathrm{d}T} \neq 0$. In these circumstances it can be seen from equation (14) that N is not a linear function of P and equation (9) shows that clearance will, therefore, not remain constant.

The model can thus reconcile the observations that, for substances excreted by tubular secretion, if P is constant clearance is independent of P and remains the same for all values of P (provided tubular saturation does not occur). If P varies, however, clearance will not remain constant, but will vary as a function of P and N. This effect is due to the accumulation of material in the renal interstitial fluid, a factor which has not been considered in previous discussions of the kinetics of tubular secretion. It is of interest to note that such accumulation within the renal interstitial fluid may be partly responsible for the 'second phase' in radioisotope renograms[13].

Plasma disappearance curves and slope clearance. We have mentioned that numerous attempts have been made to calculate renal clearances using plasma disappearance curves, and that it was necessary to hypothesize a two-compartment distribution for *p*-aminohippurate and 'Hippuran' to explain the data obtained. The following equations will concern the disappearance curves of substances excreted by glomerular filtration alone and of substances excreted by both tubular secretion and glomerular filtration. In these derivations it is assumed that extra-renal losses are negligible and the material is distributed throughout a single homogeneous plasma compartment. Probably neither of these assumptions is strictly true; however, it will be shown that the two-compartment hypothesis is not necessary to explain why plasma disappearance curves of substances secreted by the tubules fail to show a logarithmic decline.

Q is the quantity of material removed from the plasma at time T. V_pP is the quantity of material remaining in the plasma at time T where V_p is the volume of distribution. Let D be the quantity of material administered at zero time by a single intravenous injection.

$$V_pP = D - Q \tag{17}$$

Differentiation gives:

$$V_p\frac{\mathrm{d}P}{\mathrm{d}T} = -\frac{\mathrm{d}Q}{\mathrm{d}T} \tag{18}$$

From equation (4):

$$V_p\left(-\frac{\mathrm{d}P}{\mathrm{d}T}\right) = R_3 + R_4 \tag{19}$$

From equations (3), (5) and (6):

$$V_p\left(-\frac{\mathrm{d}P}{\mathrm{d}T}\right) = K_3P + V_n\frac{\mathrm{d}N}{\mathrm{d}T} + K_5N \tag{20}$$

If a substance were excreted by glomerular filtration alone very small quantities would diffuse into the renal interstitial fluid and, as the plasma concentration declines, would diffuse back into the plasma. R_4 would be very small in comparison to the other rates and $R_5 = 0$. If $R_4 \simeq 0$, then:

$$V_p\left(-\frac{\mathrm{d}P}{\mathrm{d}T}\right) = R_3 = K_3P \tag{21}$$

$$\frac{K_3}{V_p}\int \mathrm{d}T = -\int\frac{\mathrm{d}P}{P} + C_1 \tag{22}$$

$$\frac{K_3}{V_p}T = -\ln P + C_1 \tag{23}$$

Thus a plot of log P versus T would result in a straight line of slope $-2{\cdot}303\frac{K_3}{V_p}$.

For substances excreted by both glomerular filtration and tubular secretion $R_4 \neq 0$ and $R_5 \neq 0$. Equations (20) and (13) are two simultaneous first-order differential equations of variables P and N. By solving for P we obtain the following second-order differential equation:

$$V_n V_p \frac{\mathrm{d}^2 P}{\mathrm{d}T^2} + \left[(K_1 + K_5) V_p + K_1 V_n\right] \frac{\mathrm{d}P}{\mathrm{d}T} + K_1(K_3 + K_5)P = 0 \tag{24}$$

The general solution will be:

$$P = E_1 e^{S_1 T} + E_2 e^{S_2 T} \tag{25}$$

where:

$$S_{1,2} = \frac{-B_2 \pm \sqrt{B_2^2 - 4B_1 B_3}}{2B_1} = F_1 \pm F_2 \tag{26}$$

$$\left.\begin{aligned} B_1 &= V_n V_p \\ B_2 &= (K_1 + K_5) V_p + K_1 V_n \\ B_3 &= K_1(K_3 + K_5) \end{aligned}\right\} \tag{27}$$

E_1 and E_2 are constants depending on the boundary conditions.

$$P = e^{F_1 T}\left[E_1 e^{F_2 T} + E_2 e^{-F_2 T}\right] \tag{28}$$

$$\ln P = F_1 T + \ln\left[E_1 e^{F_2 T} + E_2 e^{-F_2 T}\right] \tag{29}$$

Since the second term of the right side of equation (29) is not a constant, a plot of log P versus T would not result in a straight line. Equation (28) shows that the declination of P is a double-exponential function of T which conforms to experimental data on the disappearance of *p*-aminohippurate[8] and of 'Hippuran'[10] following a single intravenous injection.

Delay in attainment of constant clearance. The last condition to be explained by the mathematical model is the observation of Mitchie and Mitchie[3] that, following almost immediate attainment of a constant *p*-aminohippurate concentration, a delay is noted before clearance becomes constant.

The material to appear in the ureters first would be that which is excreted by glomerular filtration. There would be some delay, of course, in passage of the material through the collecting tubules, the calyces and the ureters. Tubular secretion will not occur until the material diffuses into the interstitial fluid and $N \neq 0$. Clearance will not attain a constant value until $\frac{\mathrm{d}N}{\mathrm{d}T} = 0$ when the interstitial fluid concentration attains a steady equilibrium concentration. The rate at which this occurs is dependent on the rate at which the material enters the kidney, the rate at which it diffuses into the renal interstitial fluid, the size of the renal interstitial fluid compartment, and the rate at which the tubular secretory processes remove it from the latter compartment. In any event, these processes will require a longer time than the time required for material to be filtered by the glomerulus and to appear in the urine.

The described model of the kidney proposes nothing which is not already known about the actual structure of the kidney. We believe that consideration of the renal interstitial fluid space in the excretory processes can explain several experimental observations which appear to be thus far inadequately explained.

PLASMA DIAMINE OXIDASE TITRES OF NORMAL AND PREGNANT RATS

By DR. YUTAKA KOBAYASHI

Worcester Foundation for Experimental Biology, Shrewsbury, Mass.

THE rise in the plasma-level of diamine oxidase during human pregnancy was first reported by Marcou *et al.*[1]. Attempts to find a similar change during animal pregnancy have been unsuccessful[2]. Ahlmark[3] reported that rat plasma showed a small rise in diamine oxidase during pregnancy, but this observation was attributed by Anrep *et al.*[2] to bacterial contamination. It has thus been assumed that the rise in plasma-level of diamine oxidase was peculiar to human pregnancy[2,4,5]. With the use of a new assay method for diamine oxidase developed by Okuyama and Kobayashi[6], it has now been found that rat plasma also shows a rise in diamine oxidase during pregnancy.

Female Holtzman rats were used in these investigations. Day one of pregnancy was determined either by the observation of a vaginal plug or by the presence of sperm in a vaginal smear. The rat diet of 'Purina' laboratory chow was supplemented with parsley during the experiment as a source of dietary iron.

2·5 ml. of blood was withdrawn by heart puncture under ether anæsthesia. The blood was oxalated, centrifuged in an International clinical centrifuge at maximum r.p.m. for 15 min, and the plasma removed. The plasma was heated at 50° C for 15 min to activate the diamine oxidase[7]. Then 0·75 ml. of plasma was diluted with 1·25 ml. of saline in a screw-cap culture tube and 5 μg of putrescine labelled with carbon-14 was added. The reaction mixture was incubated in a Dubnoff metabolic shaker at 37° C in air for 2 h, and the reaction product was extracted with toluene twice, according to the method previously described[6]. The amount of end-product was assayed in a liquid scintillation counter (either a Packard Tricarb, model 314 *EX* or a Nuclear Chicago, model 725S).

Table 1. AVERAGE DAILY TITRES OF PLASMA DIAMINE OXIDASE IN C.P.M. OF 12 FEMALE RATS MEASURED FOR 20 CONSECUTIVE DAYS

Day	Mean	± *S.D.*	Day	Mean	± *S.D.*

8	278		156
9	163		95
10	301		150
11	143		80
12	320		128
Mean	240		119
S.D.	65		

The relative activity of the enzyme was expressed as c.p.m. corrected for background corresponding to putrescine reaction product. The counting efficiency was approximately 50 per cent.

^{14}C putrescine dihydrochloride (New England Nuclear Corp.) was diluted with non-isotopic putrescine dihydrochloride to contain 5 μg putrescine (base)/0·1 ml. with an activity of 20,000 d.p.m./μg.

An estimate of the normal, non-pregnant plasma diamine oxidase titre for female rats was obtained by following the daily plasma titres of twelve rats for twenty successive days. The daily average plasma titres observed are presented in Table 1. It can be seen that the values ranged from 155 c.p.m. to 363 c.p.m. with about a 50 per cent standard deviation. The average diamine oxidase titres of each rat over the twenty-day period are presented in Table 2. These values ranged from 143 c.p.m. to 339 c.p.m., again with a standard deviation of about 50 per cent. These data established a frame of reference for three pregnant rats which was similarly analysed during the gestation period. These data showing the pattern of plasma diamine oxidase titres during the gestation period are presented in Fig. 1. It can be seen that there was a marked rise in the plasma diamine oxidase titre from day 9 reaching a maximum at day 13, 14 or 15, depending on the rat, and then rapidly decreasing towards parturition. Two of the three rats showed a second rise in diamine oxidase at day 19. One rat delivered at day 21 while the other two delivered at day 22. All rats had normal litters.

An analysis of variance of the results in Table 1 showed there was a significant difference among the daily average diamine oxidase titres ($P < 0·001$). A similar analysis of Table 2 showed there was a significant difference between rats ($P < 0·001$). However, in spite of these statistical differences in the normal plasma titres among the rats and the relatively high standard deviation associated with each determination, the maximum change in the plasma titre of this enzyme during pregnancy was 50-100 times the non-pregnant levels. The development of diamine oxidase during rat pregnancy, therefore, is an easily recognized event.

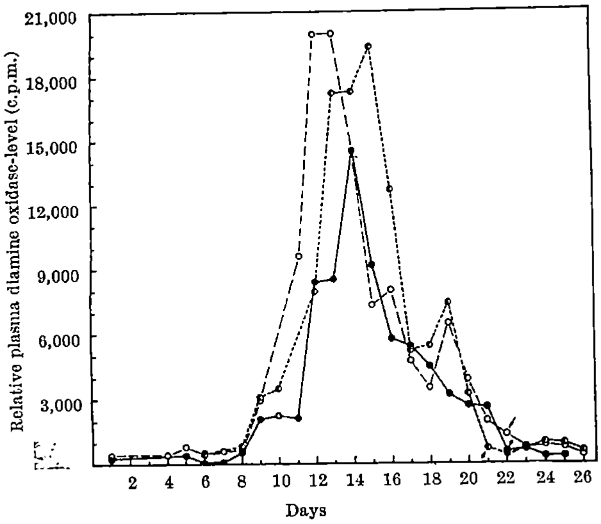

Fig. 1. Pattern of plasma diamine oxidase titres during pregnancy of three rats. Arrows indicate parturition

The pattern of diamine oxidase activity during the rat's gestation period may be correlated with the data presented by Kameswaran *et al.*[8] and Kahlson *et al.*[9]. Kahlson and his group have reported an increase in urinary excretion of free histamine by the mother rat from the fifteenth to about the twentieth day of gestation. At about the twentieth day, there was a sharp drop in the urinary excretion of histamine which was followed by parturition. The urinary histamine has been reported to be of fœtal origin[10]. Kameswaren *et al.*[8] have reported that the pregnant rat's uterus loses its sensitivity to histamine from about the tenth to the fifteenth day of gestation followed by a gradual recovery to full histamine sensitivity at about the nineteenth or twentieth day. If we focus our attention on the last six days of the gestation period, we can postulate that the three events—the drop in plasma diamine oxidase activity, the increasing sensitivity of the uterus to histamine, and the increasing excretion of free histamine (which is indicative of a higher circulating titre of histamine)—may act together to effect a histamine-dependent mechanism associated with parturition. The decreasing circulating titre of diamine oxidase would favour longer biological existence of the circulating histamine of fœtal origin in the mother. When the animal approaches term the sensitivity of the uterus to histamine returns so that the histamine may participate in the parturition process. It is unlikely that histamine and diamine oxidase can explain the complete mechanism of parturition, however, especially in view of the known action of progesterone and oxytocin[11,12]. It has been well established that a fall in progesterone titre during gestation initiates parturition in the rat. It should be recalled, however, that a fall in progesterone alone will not cause uterine tissue to contract and also histamine in the rat antagonizes myometrial contraction. Therefore, in view of the evidence presented here, it appears likely that histamine and diamine oxidase may be participants in the process of parturition in the rat.

Although there is general agreement that the rat placenta is a likely source of diamine oxidase[2,3], the stimulus required for the production and maintenance of plasma diamine oxidase is unknown. In the foregoing discussion it has been suggested that plasma diamine oxidase-levels are somehow associated with the level of circulating histamine. However, it is possible that the observed rise in plasma diamine oxidase may not, in fact, be associated with circulating histamine but with some other diamine.

I thank J. Kupelian and J. C. Dickinson for their assistance.

SIMULTANEOUS ELECTROMAGNETIC MEASUREMENT OF BLOOD FLOW IN THE MAJOR CORONARY ARTERIES

By Prof. A. KOLIN, G. ROSS, P. GAAL and S. AUSTIN

Departments of Biophysics and Surgery, University of California, Los Angeles

CORONARY artery disease is now the leading cause of death in the western hemisphere, and in the United States during the decade 1951–61 its incidence increased from 219·5 to 274·6 per 100,000 population. Furthermore, the percentage of all deaths from major cardiovascular-renal diseases attributable to coronary artery disease increased from 43 to 54 during this period[1].

These facts emphasize the need for a thorough understanding of the hæmodynamics of the coronary circulation. Until recently, however, most direct methods of measuring coronary arterial flow involved cannulation of the artery, the use of anticoagulants and variable trauma to the artery and surrounding tissues. Moreover, the measuring devices themselves often increased the resistance to the flow of blood. These shortcomings were largely overcome by the non-cannulating electromagnetic flowmeter[2], which has, in the past five years, been increasingly used in physiological investigations of the coronary circulation[3]. However, in all the reported work, flow in only one coronary artery at a time has been measured, and so only partial information has been obtained. The simultaneous measurement of flow in all the major coronary arteries would provide data on the total coronary flow and its distribution and the effects of occlusion of one major branch on flow through the other branches could readily be determined. A study of the simultaneously recorded patterns of phasic flow would also provide information regarding the strength and pattern of contraction in different parts of the myocardium. A more complete picture of the effects of drugs of pharmacological and therapeutic importance would also be possible. This article reports the successful use of the gated sine-wave electromagnetic flowmeter[4,6] to measure simultaneously blood flow in the right main coronary artery and in the anterior descending and circumflex branches of the left coronary artery in the anæsthetized dog. Flow in the anterior septal branch of the left coronary artery which carries approximately 15 per cent of the left coronary flow[5] was not determined, and since there were a few small branches proximal to the probes the combined flows measured in this investigation probably represent some 80 per cent of the total coronary inflow.

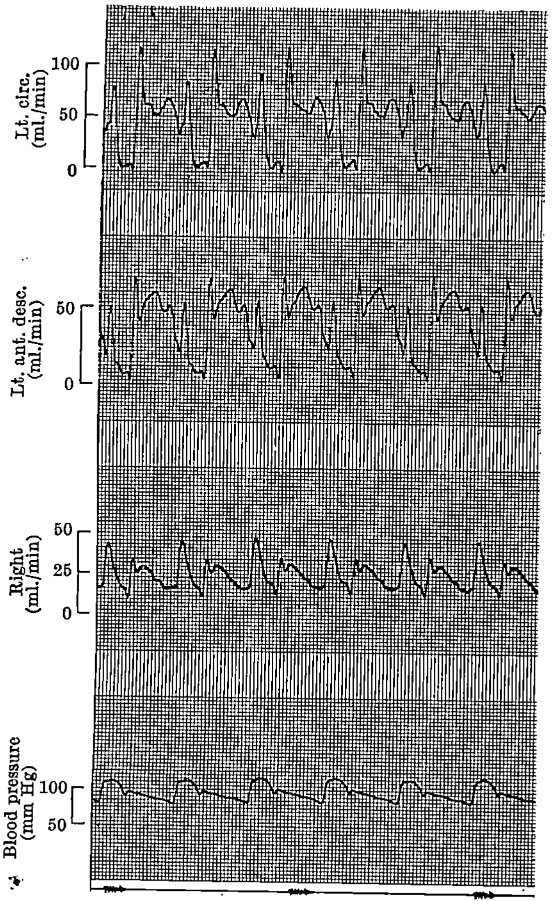

Fig. 1. Phasic blood flow in the left circumflex, left anterior descending and right coronary arteries of the anæsthetized open-chest dog. The lowest trace shows phasic arterial pressure recorded from the aortic root

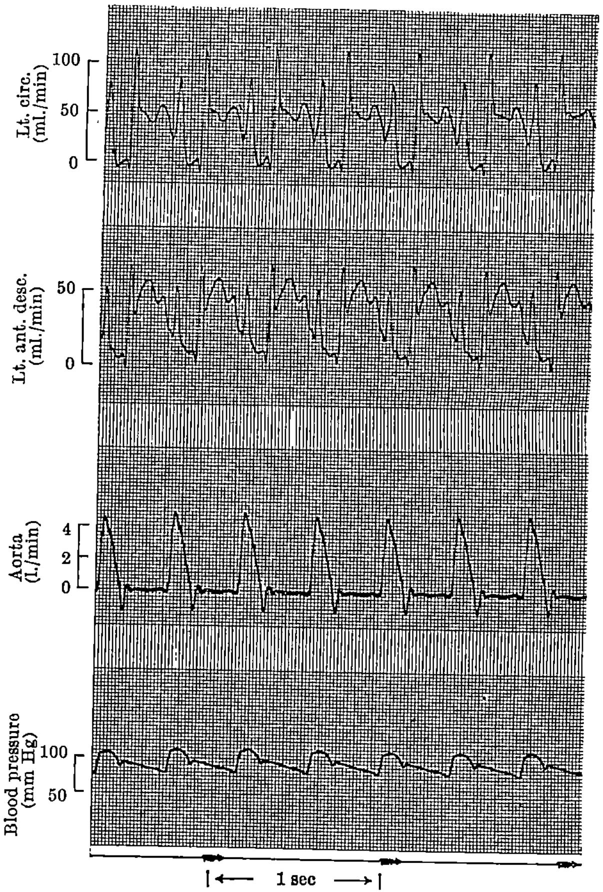

Fig. 2. Phasic blood flow in the left circumflex and left anterior descending coronary arteries and in the ascending aorta of the anæsthetized open-chest dog. The lowest trace shows phasic arterial pressure recorded from the aortic root

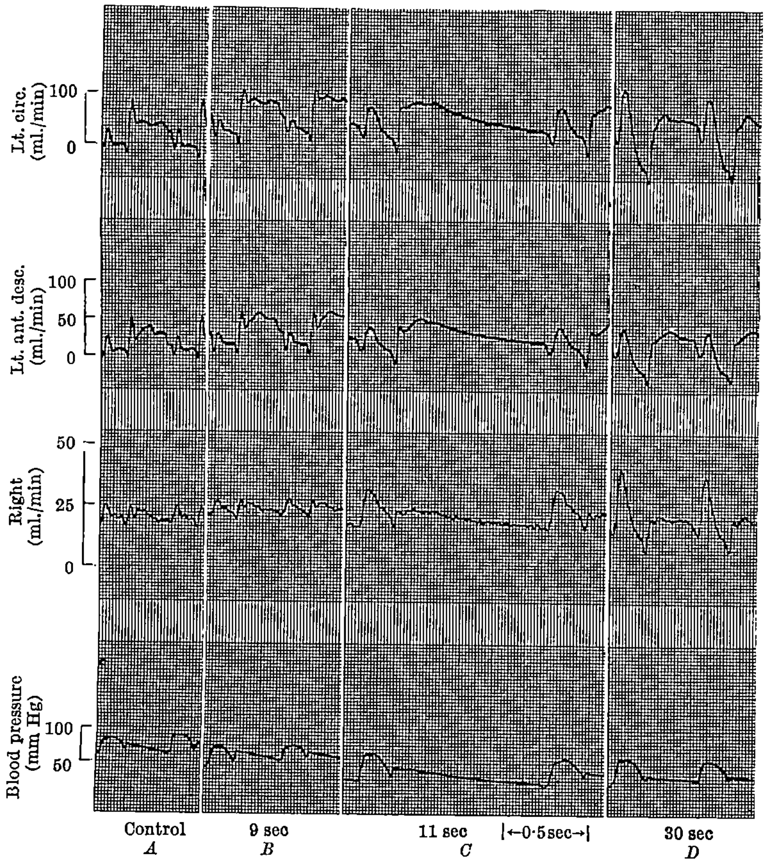

Fig. 3. Phasic aortic root pressure and phasic blood flow in the left circumflex, left anterior descending and right coronary arteries of the anæsthetized open-chest dog. *A*, control records immediately preceding the intravenous injection of 2 mg acetylcholine; *B*, *C*, *D*, record obtained 9 sec, 11 sec and 30 sec after this injection

Animals weighing 20–30 kg were anæsthetized with intravenous pentobarbitone sodium. A median sternotomy was performed and respiration was maintained with a Bird Mark 8 respirator. After opening the pericardium, 1–2 cm of the right coronary and left anterior descending coronary arteries were freed from the surrounding tissue. Access to the left circumflex coronary artery was obtained through an incision in the left fifth intercostal space. Flow probes were then placed on all three coronary arteries. Pressure at the root of the aorta was measured by a Sanborn physiological pressure transducer via a polyethylene tube introduced through the carotid artery. In some experiments a flow transducer was placed on the aortic root and flow in this vessel and in two coronary arteries was recorded. The flow probes and flow channels have been previously described[6–8]. In these experiments all three channels were energized by a common oscillator to avoid the possibility of frequency heterodyning. Calibration was performed at the end of the experiment using saline delivered by a gravity feed.

Table 1. BLOOD FLOW IN THE MAJOR CORONARY ARTERIES OF A 21-KG ANÆSTHETIZED OPEN-CHEST DOG

Heart weight 160 g, rate 150 min. Blood pressure 115/85. Duration of systole, 0·14 sec; duration of diastole, 0·26 sec

	Stroke flow (ml.)		Minute flow (ml.)			Ratio systolic: diastolic flow
	Systolic	Diastolic	Systolic	Diastolic	Total	
Left circumflex	0·07	0·24	10·5	36	46·5	1 : 3·4
Left anterior descending	0·04	0·15	6	22·5	28·5	1 : 3·8
*Total left coronary	0·11	0·39	16·5	58·5	74	1 : 3·5
Right coronary	0·07	0·09	10·5	13·5	24	1 : 1·3
*Total coronary	0·18	0·48	27	72	99	1 : 2·7

* Excluding flow in anterior septal artery.

Fig. 1 shows the phasic flows in the three coronary arteries. The general patterns are similar to those published by Khouri and Gregg[9] and Menno and Schenk[10] except for the more prominent peaks in systole and early diastole. Fig. 2, which shows simultaneous flows in the two main branches of the left coronary artery and at the root of the aorta, indicates that the upstroke of the systolic peak coincides with the beginning of aortic ejection while the upstroke of the diastolic peak corresponds to the beginning of aortic back flow.

These flow peaks are much less prominent in the absence of rigid cuffs around the aorta, such as the flow probe recording blood flow at the aortic root.

Table 1 summarizes some of the data obtained from Fig. 1. It will be noted that, unlike other arteries, flow in the coronary vessels is greater during diastole than during systole due to the impediment to flow through intramural vessels by the contracting myocardium. This impediment varies in different parts of the heart, as shown by the different systolic/diastolic flow ratios.

Fig. 3 shows the profound effect of an intravenous injection of 2 mg acetylcholine on the simultaneously recorded coronary flow patterns. After 9 sec, flow in late diastole is increased in all the coronary arteries, indicating that vasodilatation has occurred. The percentage increase in the stroke systolic flow in the right coronary artery and in the left anterior descending coronary artery is similar to the percentage increase in diastolic flow. A disproportionately large systolic flow increase has ocurred in the left circumflex coronary artery, however, indicating a considerable decrease in systolic extravascular resistance in the vascular bed of this artery. At 30 sec, vasodilatation is lessening but the stroke systolic flows have still further increased. It will also be noted that while late diastolic flow has returned to approximately the pre-injection levels in the right coronary artery and in the left anterior descending coronary artery, it remains elevated in the left circumflex coronary artery. Table 2 summarizes these changes.

The fact that the stroke systolic/diastolic flow ratio varies among the different coronary arteries in the control state and that this ratio varies to a different degree in each artery in response to a drug indicates that the coronary vascular bed is not uniform. This fact is of great importance since it means that flow changes observed in one artery following certain stimuli do not

Table 2. CHANGES PRODUCED BY INTRAVENOUS ACETYLCHOLINE 2 MG

Numbers in parenthesis indicate percentage of control values

		Before injection	9 sec after injection	30 sec after injection
	Aortic pressure	85/65	75/55	55/30
	Heart rate	150	150	143
	Duration of systole (sec)	0·14	0·14	0·14
	Duration of diastole (sec)	0·26	0·26	0·28
Lt. circ. coronary	Stroke systolic: diastolic flow ratio	1 : 13·2	1 : 4	1 : 2·1
	Late diastolic flow (ml./min)	40	80 (200%)	53 (133%)
Lt. ant. desc. coronary	Stroke systolic: diastolic flow ratio	1 : 5·2	1 : 5·6	1 : 3·3
	Late diastolic flow (ml./min)	32	50 (157%)	27 (86%)
Right coronary	Stroke systolic: diastolic flow ratio	1 : 1·8	1 : 1·8	1 : 1·3
	Late diastolic flow (ml./min)	19	24 (121%)	19 (100%)

always reflect the behaviour of the entire coronary circulation as has sometimes been assumed. It is anticipated that the simultaneous recording of flows in the major coronary arteries will lead to greater knowledge of myocardial function and coronary flow behaviour in different parts of the heart.

We would like to thank Mr. D. Ryan and Mr. P. Cox for assistance.

ISOLATION OF A SOLUBLE RNA POLYMERASE FROM RAT TESTIS

By P. BALLARD and Prof. H. G. WILLIAMS-ASHMAN

Ben May Laboratory for Cancer Research and Department of Biochemistry,
University of Chicago

AN enzyme which catalyses a DNA-dependent incorporation of nucleotides into RNA, and requiring the presence of all four major ribonucleoside triphosphates, was first detected by Weiss[1,2] in association with insoluble nucleoprotein gels prepared from rat liver cell nuclei. Afterwards, such RNA polymerases were demonstrated in other mammalian[3–5] and plant[6] tissues, and in various micro-organisms[7–10]. But extensive purification of enzymes of this class, and thorough examination of their properties, has been achieved as yet only with certain bacterial polymerases[2,8,9], which can be readily freed from DNA. Most investigations of the DNA-dependent RNA polymerase activity of animal tissues have been conducted with 'aggregate' enzyme[1] preparations derived from cell nuclei. These gels contain firmly bound DNA which cannot be removed from the RNA polymerase protein in a manner which allows unequivocal direction of polyribonucleotide synthesis by exogenous DNA[1,2,11]. There is evidence that RNA synthesis by such aggregate enzyme preparations may be limited more by the priming ability of the bound DNA than by the catalytic activity of the RNA polymerase protein[11]. This complicates interpretation of changes in the RNA polymerase activity of nuclear aggregates from various tissues which have been reported to follow from hormonal[11–14] and other[15,16] treatments.

We report here a simple procedure for isolation of a soluble RNA polymerase from rat testis. The enzyme, which is probably derived from the nuclei of various cellular elements, exhibits an absolute requirement for DNA, and is virtually devoid of DNA polymerase and ribonuclease activities. DNA clearly directs the synthesis of complementary polyribonucleotides by this testicular enzyme. Recently, Furth and Loh[17] described the partial purification of a soluble DNA-directed RNA polymerase from chicken embryos.

Testes were excised from Sprague–Dawley rats (250–400 g) and the capsules and arteries removed. The tubules were homogenized in a Waring blender at low speed with two volumes of ice-cold 0·05 M *tris*(hydroxymethyl)-aminomethane (*p*H 75) containing 0·001 M β-mercaptoethanol. The homogenate was centrifuged at 20,000*g* for 20 min at 2°. The supernatant fluid was centrifuged at 98,000*g* for 1 h. The resulting supernatant fluid was fractionated by addition of solid ammonium sulphate at 0°. The material precipitating between 20 and 42 per cent saturation was collected and dissolved in a solution of the buffered β-mercaptoethanol containing glycerol at a final concentration of 30 per cent (v/v). Further fractionation was carried out on columns (30 cm × 2 cm) of diethylaminoethylcellulose, previously equilibrated against the buffered mercaptoethanol-30 per cent glycerol solution. Approximately 750 mg of protein was run on to the column at 25°, and washed through with the same medium until the absorbancy at 280 mμ of the eluant was less than 0·1. The flow rate was about 30 ml./h, and fractions of 5 ml. volume were collected. A second fraction was eluted with buffered mercaptoethanol-30 per cent glycerol made 0·15 M with respect to ammonium sulphate. This material possessed considerable RNA polymerase activity, but it was contaminated with DNA polymerase. When the optical density at 280 mμ of the eluant resulting from application of the latter fluid reached a value of less than 0·1, further elution was accomplished with buffered mercaptoethanol – 30 per cent glycerol made 0·3 M with respect to ammonium sulphate. This material was pooled, and the protein precipitated at 2° by addition of solid ammonium sulphate to 60 per cent saturation (assuming its solubility in water rather than the aqueous glycerol solution actually present). This protein material was dissolved in 0·05 M *tris* *p*H 7·5, 0·001 M β-mercaptoethanol containing glycerol at a final concentration of 50 per cent (v/v). The ratio of the absorbancy of this protein solution at 280 mμ to that at 260 mμ was in the vicinity of 1·5. The fraction was devoid of DNA polymerase activity[18], and failed to degrade highly radioactive *E. coli* RNA labelled with phosphorus-32 to acid-soluble products[19].

Some features of the RNA polymerase activity of the partially purified testicular enzyme are summarized in

Table 1

Experiment No.	Reaction system	GMP-^{14}C incorporated into RNA (μμmoles)
1	Complete	72·0
	Omit CTP	0·7
	Omit UTP	3·0
	Omit CTP and UTP	0·7
	Omit CTP, UTP and ATP	0·5
	Omit DNA	0·6
	Omit $MnCl_2$	0·0
	Add 2 μmoles spermidine	121·0
	Add 2 μmoles spermine	111·0
2*	Complete	81·5
	Omit 2-mercaptoethanol	37·0
	Add 2·5 μg actinomycin D	11·0
	Add 10 μg actinomycin D	2·0
	Add 2 μmoles phosphopyruvate and 20 μg pyruvate kinase	80·0

Cofactor requirement for soluble testicular RNA polymerase. The complete reaction system contained: 100 μmoles *tris* buffer of *p*H 7·7; 3 μmoles of $MnCl_2$; 5 μmoles of 2-mercaptoethanol; 0·5 μmoles each of ATP, CTP and UTP; 53 μg of calf thymus DNA; 0·078 μmoles of GTP-8-^{14}C ($4·2 \times 10^6$ c.p.m. per μmole); and 280 μg protein of material eluted from the diethylaminoethyl-cellulose column by 0·3 M ammonium sulphate. The final volume was 1·0 ml. The vessels were incubated for 40 min at 37° C.

* The complete system in Exp. 2 was identical to Exp. 1 except that 0·04 μmoles GTP (8×10^6 c.p.m./μmole) and 375 μg protein were added.

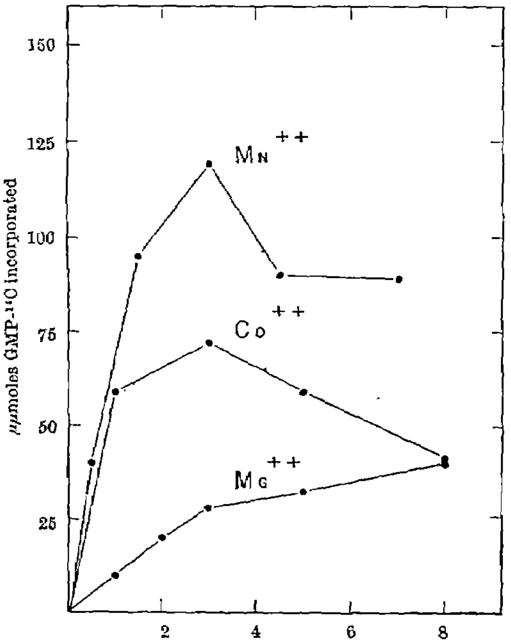

Fig. 1. The requirement of divalent cations for incorporation of GTP-8-^{14}C. The reaction vessels contained: 100 μmoles of *tris* buffer of *p*H 7·3; 0·5 μmoles each of UTP, CTP and ATP; 2 μmoles of PEP; 20 μg of pyruvate kinase; 5 μmoles of 2-mercaptoethanol; 27 μg of salmon sperm DNA; 0·048 μmoles of GTP-8-^{14}C ($8·06 \times 10^6$ c.p.m./μmole); and 470 μg of testicular enzyme. The divalent cations were present in the concentrations indicated. The total volume was 1·0 ml. Incubation proceeded for 40 min at 37°

Table 1. A virtually complete requirement for all four ribonucleoside triphosphates, for DNA, and for Mn^{++} ions was observed. The DNA-primed synthesis of RNA was also supported by Mg^{++} and Co^{++} ions as depicted in Fig. 1, but Mn^{++} ions were the most effective, especially at low levels. The incorporation of nucleotides into RNA was stimulated by β-mercaptoethanol and by polyamines. In experiments of short duration, no enhancement of nucleotide entry into RNA was observed on addition of phosphopyruvate and pyruvic kinase, suggesting that degradation of ribonucleoside triphosphates did not limit the rate of reaction. The RNA polymerase activity was inhibited by low concentrations of actinomycin *D* and inorganic pyrophosphate. The corresponding deoxyribonucleoside triphosphates could not substitute for the ribonucleoside triphosphates. Substitution of one ribonucleoside diphosphate for the corresponding triphosphate decreased the labelled nucleotide incorporation by about 50 per cent. The optimal *p*H for RNA polymerase activity was 7·7. The nucleotide incorporations were linear with respect to enzyme concentration and to time of incubation over an initial period of 40 min. Incorporation of all four labelled ribonucleoside triphosphates into RNA was observed. The system was saturated with all the four nucleoside triphosphates at a final concentration of about 0·12 mM. Maximal rates of reaction occurred at 37°. When DNA isolated from calf thymus, salmon sperm, *Micrococcus lysodeikticus*, and *T*2-bacteriophage was used as a primer, the RNA polymerase activity was optimal in each case at a final concentration of approximately 50 μg DNA per ml. of reaction mixture. Heat-denatured DNA was much less effective as a primer. In marked contrast to the RNA polymerase activity of mammalian nuclear 'aggregate' enzyme preparations, which exhibit highest activity at high ionic strengths[2,3,11], the incorporation of nucleotides into RNA by the soluble testicular enzyme was markedly depressed on raising the ionic strength above 0·1.

That the reaction product with various labelled ribonucleoside triphosphates as precursors was RNA was suggested by the fact that the acid-insoluble radioactive material was rendered acid-soluble by treatment with ribonuclease (but not with deoxyribonuclease), and also after hydrolysis in 0·3 N potassium hydroxide at 37° for 18 h. Radioactivity was detected in all four of the 2′(3′)-mononucleotide products of the base hydrolysis when any single α-^{32}P-labelled nucleoside triphosphate was used as precursor in the presence of the three complementary ribonucleoside triphosphates. When three DNA's of widely different base compositions (*M. lysodeikticus*, calf thymus, and *T*2-bacteriophage) were used as primers with either α-labelled ^{32}P-GTP or uniformly labelled ^{14}C-UTP as substrates, the extent of GMP and UMP incorporation was a reflexion of the composition of the DNA added to the system; and nearest neighbour base frequency investigations[7,10] with ester-labelled ^{32}P-GTP or -UTP provided strong evidence for direction of complementary RNA synthesis by DNAs from several different sources.

Similar testicular enzyme preparations, in a system containing the requisite ribonucleoside triphosphate precursors and Mn^{++}, failed to catalyse any polyribonucleotide synthesis in the presence of either tobacco yellow mosaic virus RNA, polyuridylic, or polycyticylic acids as primer. Such experiments were carried out under conditions where rates of reaction equivalent to 5 per cent of those found with DNA's as primers could have been readily detected. These findings are in marked contrast to those obtained with certain refined bacterial RNA polymerases, which readily catalyse RNA-directed as well as DNA-directed RNA synthesis[19,20].

When rat testis tubules were comminuted in hypotonic solutions as described here, considerable quantities of the RNA polymerase were found in the supernatant fluid resulting from ultracentrifugation of the homogenate. But if the testicles were homogenized in isotonic sucrose containing 1 mM magnesium chloride, then considerable amounts of RNA polymerase, later extractable with hypotonic buffers, were associated with the 'nuclear' fraction which sedimented on centrifugation at 600*g*. Application of the methods recorded here to rat prostate[11] failed to render soluble any appreciable RNA polymerase activity. The factors which permit the facile solubilization of the RNA polymerase from testis and embryonic tissue[17] as compared with certain other mammalian cells[4,11] remain obscure, but the presence of a relatively large number of dividing cells may be important in this respect.

RESISTANCE OF INFECTIOUS RNA AND TRANSFORMING DNA TO IODINE WHICH INACTIVATES f_2 PHAGE AND CELLS

By PROF. YU-CHIH HSU

Environmental Microbiology Laboratory, Department of Sanitary Engineering, School of Hygiene and Public Health, Johns Hopkins University, Baltimore, Maryland

THE greater stability and general utility of iodine and certain of its organic derivatives compared to its chlorine counterparts are probably responsible for their use as sterilizing agents in hospitals, surgical areas, and for the disinfection of drinking-water, swimming-pool water, and eating utensils. The effect of elemental iodine on viruses, however, is not consistent. Two apparently opposite results were reported on enteric viruses and on tobacco mosaic virus (TMV). Elementary iodine was found to destroy the infectivity of enteric viruses including polio, coxsackie and echo virus[1], yet TMV[2,3] and, recently, TMV–ribonucleic acid[4] were resistant to iodine.

Since the iodide ion concentration in a reaction mixture significantly influences the rate of iodination of tyrosine in proteins it would not be surprising if the apparent discrepancy in the viricidal action of iodine were due to differences in the iodide concentration in the reaction mixtures.

In the present investigations, the iodide concentration in reaction mixture was appropriately considered as the bactericidal and viricidal action of iodine was examined. Despite its powerful bactericidal and viricidal action in minimal iodide ion concentration, iodine did not produce appreciable destruction of either infectious RNA or DNA.

Infectious RNA from iodinated phage. The RNA bacterial phage was kindly supplied by Dr. N. D. Zinder through Dr. T. Fukasawa. The purification of phage was essentially the same as described by Loeb and Zinder[5]. In order to test the biological activity of infectious RNA from phage inactivated with iodine, partially purified f_2 phage, having 1×10^{13} per ml. of plaque-forming unit, was treated with 0·2 mM of iodine containing 0·24 mM of potassium iodide for 20 min. The phage survival was 0·0018 per cent, or about 5 logs of inactivation. After reduction of the residual iodine by sodium thiosulphate, the RNA was extracted and compared to that extracted from un-iodinated phage. The RNA extraction procedure used was similar to that described by Paranchych[6] with a slight modification. It was found that the infectivity of the RNA extracted from these two preparations was the same, that is, the inactivated phage yielded infectious RNA in quantity indistinguishable from that of normal phage (Table 1). Such a result suggests that either the protein coat of the phage is so compact that iodine cannot reach the RNA or that the RNA is insensitive to iodine, or both.

Iodine resistancy of infectious RNA. To test the sensitivity of infectious RNA to iodine $2 \cdot 6 \times 10^6$ plaque-forming unit of f_2 RNA was treated with 0·4 mM iodine containing 0·48 mM potassium iodide for 10 min at room temperature (27° C). The iodine colour persisted even at the end of the reaction. As shown in Table 2, the infectious RNA activity was completely resistant to treatment with iodine.

From these results it is quite clear that inactivation of phage by iodine in minimal amounts of potassium iodide may be attributed to its action on the protein coat of the phage. The reaction of iodine with protein is well known, and includes oxidation of sulphydryl groups or substitution into the tyrosyl or histidyl moieties[7]. Since f_2 phage has no histidine residue in its protein coat[8], reaction of iodine with the sulphydryl and tyrosyl groups need not be considered, although tryptophanyl residues could be involved. *Para*-chloromercuribenzoate (PCMB), a sulphydryl attacking agent, in 10^{-3} M solution did not inactivate f_2 phage in *p*H 8 *tris* buffer in 60 min contact at room temperature, in contrast to *E. coli* which was inactivated completely within several seconds by the same concentration of this agent. This leaves the reaction of iodine with tyrosyl and perhaps tryptophanyl residues as responsible for the loss of infectivity of f_2 phage.

Table 1. IODINATION OF INTACT PHAGE AND INFECTIVITY OF ITS RNA

Iodination	Infectivity (PFU per ml.) Before iodination	After iodination	Survival (%)	Infectious RNA found
0·2 mM for 20′, at room temperature	10×10^{12}	$1 \cdot 8 \times 10^8$	0·0018	$3 \cdot 25 \times 10^6$
Control	10×10^{13}	10×10^{12}*	100	$3 \cdot 65 \times 10^6$

* Control was treated with thiosulphate only.

Partially purified f_2 phage in *p*H 7 of PBS was iodinated with 0·2 mM (50 mg/l.) of iodine which, containing 0·24 mM of potassium iodide, at room temperature for 20 min, at the end of reaction residual iodine was reduced by sodium thiosulphate. The infectious RNA of both iodinated phage and control of non-treated phage was extracted and assayed for infectivity by the method described in the text.

Table 2. RESISTANCE OF INFECTIOUS f_2 RNA TO IODINE

	Infectivity (PFU/ml.)
Iodination by 0·4 mM I_2 containing 0·48 mM KI at room temperature for 10 min	$2 \cdot 42 \times 10^6$
Control	$2 \cdot 55 \times 10^6$

The infectious RNA extracted from 10^{13} PFU/ml. was diluted with PBS and iodinated with 0·4 mM of iodine containing 0·48 mM of potassium iodide at room temperature for 10 min. At end of reaction, residual iodine was reduced with sodium thiosulphate and activity was measured.

Comparison of iodination of tyrosine to iodine inactivation of phage. Tyrosine is the amino-acid residue most likely to be attacked by iodine at neutral *p*H, and room temperature. In examining the action of iodine on tyrosine, Li[9] noted that the iodide ion retards the reaction. In the present investigation the iodination of tyrosine was performed under conditions comparable to those used for inactivation of phage. L-Tyrosine (Calbiochem) was

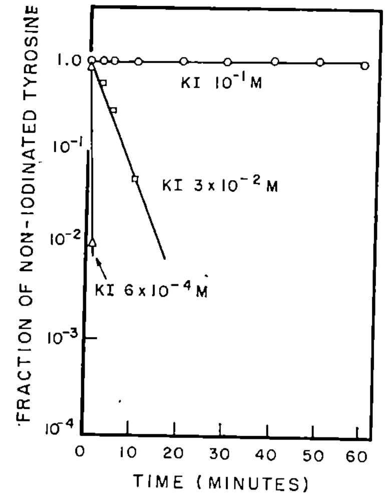

Fig. 1

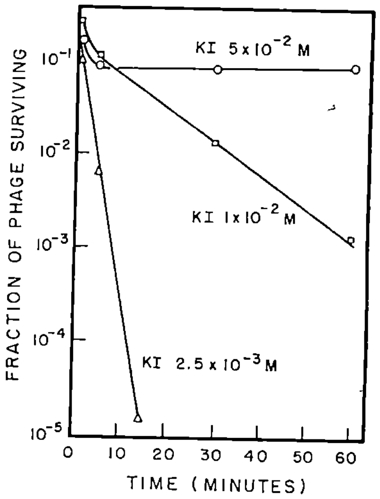

Fig. 2

Fig. 1. Effect of varying amounts of potassium iodide on iodination of tyrosine in 0·05 M PBS (*p*H 7) at room temperature using $1 \cdot 25 \times 10^{-4}$ M of 1-tyrosine and 5×10^{-4} M iodine

Fig. 2. Effect of potassium iodide concentration on rate of phage inactivation with 0·04 mM of iodine in 0·05 M PBS (*p*H 7) at room temperature

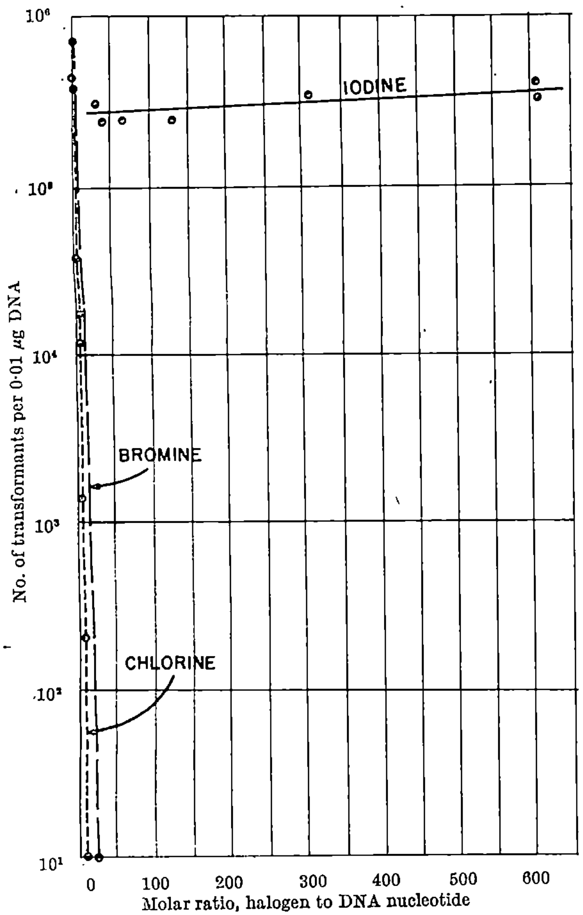

Fig. 3. Effect of iodine, chlorine and bromine on transforming DNA. The number of transformations per 0·01 μg of DNA remaining after reaction with different halogen is plotted against the initial halogen concentration

dissolved in pH 7, 0·05 M phosphate buffer, containing 0·14 M sodium chloride (PBS). Iodotyrosine was determined from the absorbancy at 312 mμ of wave-length[10]. As shown in Fig. 1, iodination of tyrosine was very rapid in 0·6 mM potassium iodide with 0·5 mM iodine, whereas in 100 mM of potassium iodide and the same level of iodine, only 5 per cent of tyrosine is iodinated. Thus the conditions which inhibit iodination of tyrosine (Fig. 1) also inhibit the inactivation of phage by iodine as shown in Fig. 2.

Action of halogen on transforming deoxyribonucleic acid (DNA). The purified transforming DNA containing less than 1 per cent of protein was extracted from strains of *Haemophilus influenzae* resistant to streptomycin (S^r), cathomycin (C^r), erythromycin (E^r), and kanamycin (K^r), and in addition, a strain which utilized protoporphyrin (PP-) in the dark in place of hæmin[11] was used. The DNA was dissolved in 0·1 M phosphate buffer–saline (PBS), and mixed with the halogen under different conditions of time, pH, temperature and concentration. Samples of the reaction mixture were stopped by diluting into 10^{-3} M solution of sodium thiosulphate. The residual transforming activity in these samples was then determined by incubating with competent *H. influenzae*, and then plating in agar containing individual antibiotics[12] or with protoporphyrin instead of hæmin and cultured in the dark.

Summarized in Fig. 3 are the results of a series of experiments in which the number of transformations per 0·01 μg of transforming DNA remaining after reaction with different halogens is plotted against the initial halogen concentration. It is clear from these results that the transforming activity was destroyed by chlorine and bromine, but not by iodine. Even after 4 h of contact at 37° C with 2 mM (500 mg/l.) of iodine in 2·4 mM potassium iodide, all five genetic markers (S^r, C^r, E^r, K^r and PP) were almost fully active. In some experiments DNA survived reaction with iodine at 45° C and pH 8·5. Heat-denatured DNA was also resistant to iodine. Dialysis of DNA after treatment with iodine-131 left no detectable iodine bound to the nucleic acid, so there could have been no addition or substitution reaction of iodine. The iodine also failed to change the ultra-violet absorption of the nucleic acid which was in contrast to the effect of chlorine which flattened the ultra-violet absorption curve.

High concentrations of a commercial organic iodine (Wescodyne) acting for several hours failed to reduce appreciably the transforming activity of DNA.

In a manner resembling somewhat the work on phage, it was found that fully active transforming DNA was extracted from *H. influenzae* which had been treated with 100 lethal doses of iodine (2 mM or 500 mg/l.).

Since iodine and its organic derivatives are commonly used as disinfectants, RNA and DNA resistance to iodine may have special significance. Inactivation of viruses by iodine might merely mean modification of its protein coat, and the genetic properties—particularly the replicability—could be preserved.

Evidence has been presented indicating that f_2 phage inactivation by iodine is due to its action on the protein component. Conditions which affect the phage inactivation also change the iodination of tyrosine in a comparable manner. It was shown by Anson *et al.*[2] that, even in high concentrations of potassium iodide, iodine oxidized —SH groups of protein or viruses. Choppin *et al.*[13] and Allison *et al.*[14] have reported that some viruses are resistant to some —SH reacting agents. The following cases may indicate an explanation for this effect: (1) —SH groups are buried deep in the molecule and are not accessible to iodine. (2) Protein coat of virus does not contain —SH groups such as myosin[15]. (3) —SH groups are not essential for the virus infection and multiplication, as the case of TMV[2].

Only 10 per cent of f_2 phage activity was recoverable after a few seconds of contact with iodine even in 0·5 M concentration of potassium iodide. In this concentration of potassium iodide, iodine reaction with tyrosine would not have been detected for hours. It does not appear likely that 90 per cent loss of activity was due to iodination of tyrosine residues in the protein coat. No explanation for this result can be offered at this time.

These investigations were sponsored by the Committee on Environmental Hygiene and supported in part by the U.S. Army Medical Research and Development Command and a U.S. Public Health Service training grant in environmental science.

I thank Dr. R. M. Herriott and Dr. C. W. Krusé for their advice, Dr. S. Nomura for her co-operation, and Misses Annabel Lindley and Carole Beach for assistance.

Note added in proof. Work at present being carried out in our laboratory by Dr. Nomura indicates that infectious polio RNA is fully resistant to iodine as the f_2 RNA. Also, the disinfection of the polio virus by iodine is inhibited by the presence of the iodide ion.

Para-O-METHYLATION OF DOPAMINE IN SCHIZOPHRENIC AND NORMAL INDIVIDUALS

By FREDERICK A. KUEHL, jun., MARTIN HICHENS, ROBERT E. ORMOND, Dr. M. A. P. MEISINGER, PAUL H. GALE, VINCENT J. CIRILLO and Dr. NORMAN G. BRINK

Merck Sharp and Dohme Research Laboratories, Division of Merck and Co., Inc., Rahway, New Jersey

SEVERAL recent publications have concerned the unique occurrence of 3,4-dimethoxyphenethylamine in the urine of schizophrenics[1–3]. Although suggestions have been made that this might be of dietary origin, there remains the possibility that it represents the product of an abnormal metabolism of dopamine, and may be intimately involved in the ætiology of the disease. In the concluding stages of the present work, Friedhoff reported[4] that di-*O*-methylation of dopamine occurs *in vitro* when the substrate is incubated with a liver biopsy homogenate obtained from a schizophrenic patient known to excrete dimethoxyphenethylamine, and further that di-*O*-methylation of administered labelled dopamine can be demonstrated *in vivo*. Thus the question of dietary origin seems to have been settled. There has, however, been no report of results of similar tests made with normal individuals.

Axelrod *et al.*[5] have noted that "successive replacement of phenolic hydroxyl groups of sympathomimetic amines is known to shift the pharmacological activity from the peripheral to the central nervous system"; Michaux and Verly[6] have reported 3,4-dimethoxyphenethylamine to be a more potent catatonic agent than the 3-methoxy-4-hydroxy derivative; and Ernst[7] has noted the catatonic activities of dimethoxy and 3-hydroxy-4-methoxyphenethylamine, finding the 3,5-dimethoxy-4-hydroxy derivative inactive in cats. Methylation in the 3-position represents a normal pathway of catecholamine metabolism *in vivo*, these derivatives (and catabolites) appearing in urine. However, *in vitro*, catechol-*O*-methyl transferase (COMT) affords a mixture of the 3- and 4-*O*-methyl derivatives. The latter, however, have not been found in urine except in the cases of arterenone, adrenalone and dihydroxyacetophenone[8]. It is possible that the presence of 4-*O*-methyl derivatives of epinephrine, *nor*epinephrine and dopamine could have been missed since no chromatographic system has been reported which adequately resolves a mixture of the 3-hydroxy-4-methoxy and 4-hydroxy-3-methoxy compounds. Resolution of the derivatives formed by coupling with any of several diazonium salts did not prove completely satisfactory in our hands[9]. Daly *et al.*[8] have oxidized *normeta*nephrine and *norpara*nephrine to vanillin and isovanillin for identification purposes. The object of the present work was to confirm Friedhoff's initial observations, to look for evidence of 3-hydroxy-4-methoxy catecholamine metabolites in urines, and to examine COMT products for di-*O*-methylated materials.

Using Friedhoff's techniques[1], we were unable to obtain unequivocal evidence of the presence of dimethoxyphenethylamine in schizophrenic urines, due to the presence of other materials in the same region of the papergram, nor did we find two-dimensional systems similar to that described by Takesada[2] as satisfactory as the technique afterwards developed. Further, our methods effect excellent resolution of basic urinary metabolites including the isomeric 3-hydroxy-4-methoxy and 4-hydroxy-3-methoxy analogues of dopamine, epinephrine and *nor*-epinephrine.

Urine samples were hydrolysed with acid and passed over a column of 'Dowex 50(H$^+$)' at *p*H 5. After washing successively with water, 0·1 N sodium acetate and water again, the basic compounds were eluted with 1 N ammonia in 65 per cent ethanol, concentrated, adjusted to *p*H 5 and taken to dryness[10]. The residue, in water, was divided into aliquots equivalent to an amount of urine containing 1 g of creatinine, adjusted to *p*H 10·3 and each aliquot (2 ml.) extracted with four 2-ml. portions of *iso*amyl alcohol–toluene (3 : 2). The organic layer was re-extracted with 0·05 N hydrochloric acid, and the extract dried under nitrogen. The bases in the residue, which include the 3-hydroxy-4-methoxy and 4-hydroxy-3-methoxy analogues of dopamine not separable by Friedhoff's procedure, were chromatographed as described here for separation and identification. To obtain a cleaner chromatogram for dimethoxyphenethylamine *estimation*, the mixture was further purified by extraction into chloroform from an aqueous solution adjusted to *p*H 9·5. The material was applied in methanol to one corner of a 20 cm × 20 cm silica gel ('Silica Gel *G*', E. Merck Acc. Stahl 7731) thin-layer plate, and chromatographed in 1-butanol–acetic acid–water (4 : 1 : 1) and air dried. The plate was then developed in a direction at right angles to the first, using 1-butanol–ethyl acetate–15 N aqueous ammonia (3 : 1 : 1). For estimation of the dimethoxy compound, 200 mg creatinine equivalent of material was used per chromatogram, while half this quantity was used for identification of other metabolites. To aid in identification and quantitation, appropriate amounts of known compounds were applied outside the limits of the solvent fronts. Identity and the almost quantitative recovery of the compounds of interest from urine were established by adding known amounts of these to urine prior to the isolation procedure, and comparison with isolates from unadulterated urine after two-dimensional chromatography. Catecholamine metabolites having a 3-hydroxyl group were detected by spraying first with 0·1 per cent alcoholic 2,6-dichloroquinone-chlorimide, and then with 0·2 per cent ninhydrin in pyridine – acetic acid – acetone (1 : 4 : 95). For quantitation, the first spray alone was used. Dimethoxyphenethylamine was better estimated on plates sprayed only with ninhydrin, 1 μg being readily detectable. As may be seen in Fig. 1, compounds of interest were separated and zones well defined.

Dimethoxyphenethylamine was not detected in any of ten normal urines. Of a group of twelve schizophrenics*, five excreted this compound, and in another group, two of ten†. The higher percentage in the first group may reflect the larger proportion of acute cases. The quantity of this metabolite varied from 10 to 3 μg/g urinary creatinine. The rather lower incidence of this compound in our limited study, as compared with previous reports (57 of 62 (ref. 2), 15 of 19 (ref. 1)), we attribute at least partly to a more selective isolation and chromatographic procedure, eliminating false positive results.

Sen and McGeer[3] found a new urinary metabolite, 4-methoxyphenethylamine, in eleven of twenty-two schizophrenic urines, but no examination of normal urines was

Fig. 1. Thin-layer chromatograms of urine extracts

(*A*) sprayed with ninhydrin; (*B*) sprayed with dichloroquinone-chlorimide. In both cases the sample was applied at the lower right-hand corner. Numbered spots are: compound isographic with but not identical to 3-hydroxy-4-methoxyphenethylamine (1), 3-methoxy-4-hydroxyphenethylamine (2), 3,4-dimethoxyphenethylamine (3), *para*nephrine (4), *norpara*nephrine (5). Spots represented as dotted circles did not appear in unadulterated urine extracts. Colours designated are: grey (*G*), black (*BK*), blue (*BL*), brown (*B*), purple (*P*), yellow (*Y*)

reported. We found a compound isographic with 3-hydroxy-4-methoxyphenethylamine, and reacting similarly with dichloroquinone-chlorimide and ninhydrin. However, by eluting this compound from the thin-layer plate and re-chromatographing in methanol-1-butanol–benzene–water (2 : 1 : 1 : 1) on Whatman 3 *MM* paper pretreated with 2·5 per cent sodium carbonate, it was shown that our tentative identification was incorrect. The compound was not further identified, nor was it peculiar to the schizophrenic urines. We were unable to detect the 3-hydroxy-4-methoxy analogues of dopamine, epinephrine or *nor*epinephrine‡ in any of the urines examined.

In our investigations with purified rat liver COMT, the alkaline solvent described in our thin-layer separation was used to confirm earlier findings[9] that dopamine is converted to both 3-hydroxy-4-methoxyphenethylamine and 4-hydroxy-3-methoxyphenethylamine. Both products were visualized by spraying the plate with Folin's reagent and were isographic with the authentic materials both on silica gel and paper. Quantitation was achieved by use of *S*-adenosyl-L-methionine-methyl-^{14}C. The ratio of 3-hydroxy-4-methoxy to 4-hydroxy-3-methoxyphenethylamine was found to be 4 : 1, and this ratio did not change significantly throughout the duration of incubation for 1 h with measurements at 5, 10, 15, 20 and 60 min. Nor was the ratio different when a crude COMT preparation from rat liver or brain was used. This may suggest that a single enzyme gives rise to both products. Although formation of the di-*O*-methyl derivative cannot be completely ruled out, we were unable to find definite evidence for its formation, by rat liver, using either dopamine or one of the mono-*O*-methyl derivatives as substrate. Incorporation of radioactivity occurred when 3-hydroxy-4-methoxy or 4-hydroxy-3-methoxyphenethylamine was incubated with the enzyme and *S*-adenosyl-L-methionine-methyl-^{14}C, more in the case of the latter substrate. In each case, partial conversion to the isomer occurred. Interconversion of some *O*-methyl catechols has been demonstrated *in vivo*, and *O*-demethylation has been demonstrated *in vitro*[8]; however, the interconversion with purified COMT does not seem to have been reported previously.

In conclusion, we have developed an improved method for the separation and identification of some catecholamines, have used it to confirm the unique occurrence of 3,4-dimethoxyphenethylamine in the urine of schizophrenic patients and noted the probable greater frequency of excretion in acute patients. There is no indication in our investigation that 3-hydroxy-4-methoxy analogues of catecholamines are formed *in vivo* by COMT, since no such derivative of dopamine, epinephrine or *nor*epinephrine was detected in urine. Our experiments with rat COMT *in vitro* indicate that this enzyme does not cause di-*O*-methylation. On the other hand, interconversion of the 3- and 4-*O*-methyl group of hydroxy-methoxy phenethylamine by COMT and *S*-adenosyl-L-methionine is reported for the first time, and the absence of 3-hydroxy-4-methoxy metabolites of catecholamines in urine may reflect this interconversion *in vivo*, although there is evidence in rats that administered paranephrine is excreted without change[8].

We must emphasize the fact that our enzyme experiments were performed with COMT from rats. Takesada *et al.*[2] were not able to detect dimethoxyphenethylamine in the urine of rats dosed intramuscularly with dopa, dopamine, or *nor*epinephrine. Friedhoff[11] has commented on this, and has used schizophrenic patients for his metabolite studies[4], but the methodology differs from that of the Japanese authors in that smaller quantities of labelled dopamine were given by intravenous infusion. His *in vitro* experiment also differed from our rat liver experiments in that a homogenate of a biopsy specimen from a schizophrenic known to excrete the corresponding phenethylamine was used, and dimethoxyphenylacetic acid rather than the amine was detected.

CYTOLOGICAL DETERMINATION OF THE HOMŒOLOGY OF CHROMOSOMES OF *Triticum aestivum*

By DR. RALPH RILEY and VICTOR CHAPMAN
Plant Breeding Institute, Cambridge

THE 42-chromosome hexaploid wheat of agriculture, *Triticum aestivum*, arose through allopolyploid evolution by the combination of the chromosome sets of the three related diploid species, *Triticum monococcum*, *Aegilops speltoides* and *Aegilops squarrosa* (all $2n = 14$). In the karyotypically primitive forms of *T. aestivum*, like the variety 'Chinese Spring', the chromosomes of the original diploid ancestors are structurally unchanged. Moreover, the original genetical equivalence of corresponding, homœologous, chromosomes derived from different diploid ancestors is still retained to a considerable extent.

This was demonstrated by Sears[1], who showed that all the 40-chromosome nullisomics of *T. aestivum*, deficient for each chromosome pair in turn, have pronounced phenotypic abnormalities. By contrast, the phenotypes are normal for plants that, in certain combinations, are simultaneously nullisomic for one chromosome and tetrasomic for a second. Apparently the chromosome in extra dosage compensates for the disturbances normally caused by nullisomy, indicating similarities in the genetic activities of the two chromosomes concerned. Nullisomic–tetrasomic compensation permits the classification of the 21 pairs of chromosomes into seven groups each of three pairs. Within each group there is good compensation in any nullisomic–tetrasomic combination, but between groups there is little, or no, compensation. Moreover, within each group one pair of chromosomes falls into each genome and was thus derived from a different diploid ancestor of the hexaploid[2]. Pairs of chromosomes in the same group are therefore homœologous, being genetically corresponding derivatives of the ancestral diploid species. This correspondence of homœologues may be presumed to be due to their origin from the same chromosome of a remote common progenitor of all three ancestral diploid species.

Only bivalents are formed at meiosis in *T. aestivum*, and there is disomic inheritance. Each chromosome therefore pairs only with its single fully homologous partner and there is normally no meiotic association between homœologues. The absence of homœologous pairing has been shown to be due to a genetic activity of a single chromosome, number *5B* (refs. 3, 4, 5). In plants deficient for this chromosome homœologous pairing occurs, although the deficiency of no other chromosome produces similar changes in the course of meiosis.

In most hybrids between *T. aestivum* and 14-chromosome diploid species in the genera *Aegilops*, *Secale* and *Agropyron* there is little chromosome pairing at meiosis, presumably because homœologous synapsis is precluded by the unmodified effect of chromosome *5B*. By contrast, in hybrids between *T. aestivum* and the diploid species *Aegilops speltoides* or *Aegilops mutica* there is considerable meiotic pairing, indeed cells occur in which all 28 chromosomes have undergone synapsis and chiasma formation[6]. Bivalents, trivalents and quadrivalents are common, and Riley, Unrau and Chapman[7] were led to propose, from pairing of this nature, that the activity of chromosome *5B* is suppressed in the presence of the genotype of *A. speltoides*. On this hypothesis the pairing is homœologous and the largest configurations—quadrivalents—result from the association of all three chromosomes of some homœologous groups of *T. aestivum* together with, in each case, the corresponding chromosome of *A. speltoides*.

The work recorded here was designed to determine the relationships of the chromosomes of *T. aestivum*, which pair meiotically in the presence of the genotype of *A. speltoides*. It was further anticipated that if, as was expected, the paired chromosomes proved to be homœologous, information would be gained about the structural equivalence of individual arms of the homœologues compared.

Since, at meiosis, it is impossible to distinguish the chromosomes of *T. aestivum* morphologically, it was necessary to mark those examined by introducing distinctive structural conditions. For this purpose use was made of the set of lines, produced by E. R. Sears in the variety 'Chinese Spring', in which each chromosome in turn is represented by a pair of telocentrics for one arm, the other arm being completely deficient. Plants with disomic telocentric conditions for different known chromosomes were crossed together to produce derivatives in which two pairs of chromosomes each consisted of one normal and one telocentric member. These derivatives were pollinated by *A. speltoides* to produce 28-chromosome hybrids which were selected for the presence of two telocentric chromosomes. Such *T. aestivum* × *A. speltoides* hybrids carried telocentrics of two different, and known, chromosomes of *T. aestivum*.

Emphasis in this first exploration of the technique was concentrated on simultaneously marking two chromosomes of homœologous group 5, or one of the chromosomes of group 5 and one of those of either group 3 or group 6. Before naming the chromosomes concerned it should be interpolated that, in the designation of the chromosomes of *T. aestivum*, the number represents the homœologous group and the letter the genome to which each belongs. The chromosomes of homœologous group 5 are thus *5A*, *5B* and *5D*, while those of groups 3 and 6 are respectively *3A*, *3B*, *3D* and *6A*, *6B*, *6D*. *T. aestivum* × *A. speltoides* hybrids were produced with the following two *Triticum* chromosomes simultaneously marked by being telocentric:

(*a*) Within homœologous group 5

5A–*5B* *5B*–*5D*

(*b*) Between homœologous groups

3A–*5A*	*3B*–*5B*	*6B*–*5B*
3A–*5B*	*3D*–*5D*	*6D*–*5B*
3B–*5A*	*6B*–*5A*	*6D*–*5D*

The behaviour of the two telocentrics, relative to each other, was investigated at first metaphase of meiosis in all these hybrids using permanent Feulgen-propionic orcein squashes of pollen mother cells. In hybrids, in which the telocentrics were in different homœologous groups, the marked chromosomes never participated in the same configuration. Either one or both of them occurred in bivalents, trivalents or quadrivalents in the many cells examined, but they were always associated with complete chromosomes and never with each other (Fig. 1*a*).

By contrast, in the hybrids in which chromosomes *5A* and *5B* or *5B* and *5D* were simultaneously marked, the telocentrics associated together in the same configurations. In some cells both telocentrics were not paired, and in others both paired with a complete chromosome in separate bivalents (Fig. 1*b*). They also participated together in configurations that were similar whether the

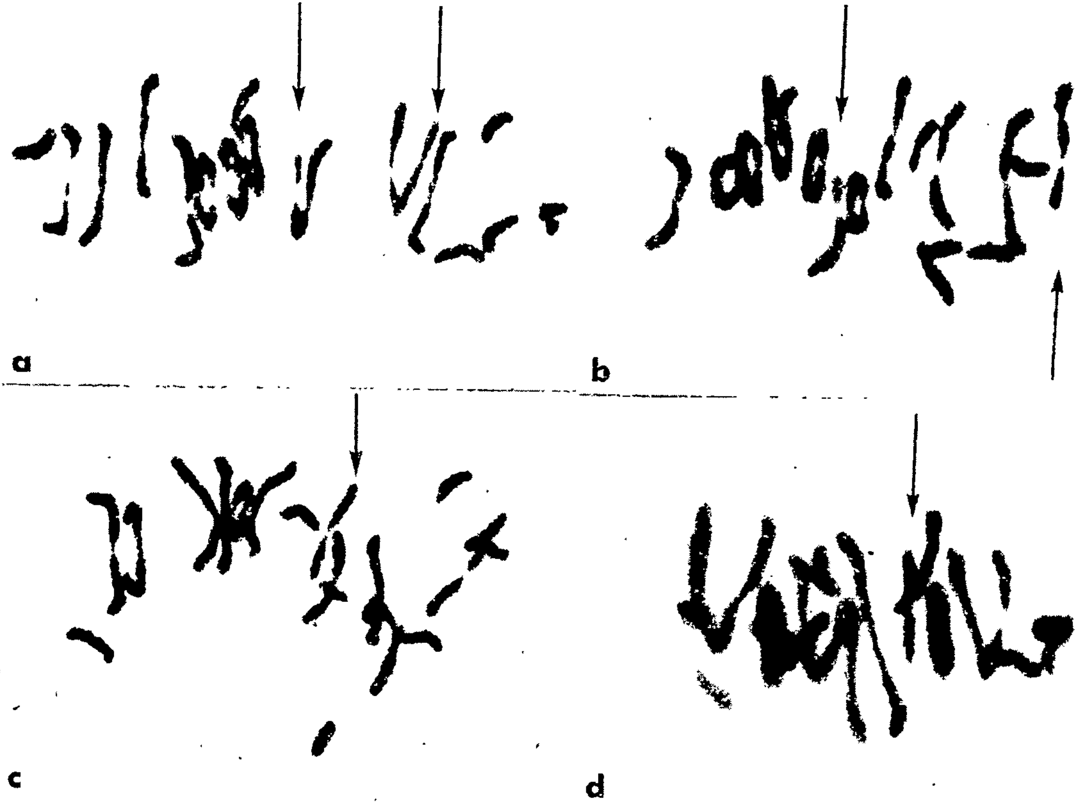

Fig. 1. First metaphase of meiosis in *T. aestivum* × *A. speltoides* hybrids with two chromosomes of *T. aestivum* simultaneously telocentric. (*a*) Three trivalents, seven bivalents and five univalents, telocentrics of 5*D* and 6*D* in different trivalents (arrowed); (*b*) one trivalent, eleven bivalents and three univalents, telocentrics of 5*B* and 5*D* in separate bivalents (arrowed); (*c*) one trivalent, ten bivalents and five univalents, telocentrics of 5*B* and 5*D* paired together in a bivalent (arrowed); (*d*) cell partly out of focus, but in focus a trivalent containing the telocentrics of 5*A* and 5*B* and a complete chromosome (arrowed)

telocentrics were 5*A* and 5*B* or 5*B* and 5*D*. The following patterns of association occurred:

(*a*) The two telocentrics paired together to form a rod-shaped bivalent (Fig. 1*c*).

(*b*) The two telocentrics were associated with a complete chromosome to form a triradial trivalent (Fig. 1*d*).

(*c*) The two telocentrics were associated with two complete chromosomes to form a quadriradial quadrivalent.

(*d*) The two telocentrics associated with two complete chromosomes to form a chain-of-four quadrivalent, in which the telocentrics were at opposite ends of the chain.

If the initial classification into homœologous groups, by the use of genetic criteria, is accepted, these observations can be interpreted as confirming that in the presence of the genotype of *A. speltoides* homœologous meiotic pairing occurs, presumably because of the suppression of the restrictive activity of chromosome 5*B*. Alternatively the capacity of chromosomes 5*A*, 5*B* and 5*D* to pair at meiosis may be regarded as demonstrating their cytological homœology independently of any preconceived notions of their relationships. By the determination of the chromosomes, which although not strictly homologous are capable of meiotic pairing, an unequivocal recognition of homœology is possible in cytological terms.

Moreover, the use of the present technique permits a further refinement in the understanding of the cytogenetic structure of *T. aestivum*. The telocentrics used, of chromosomes 5*A*, 5*B* and 5*D*, are revealed to represent equivalent arms of all three homœologues, because they are capable of pairing together directly. The arm of 5*A* present as a telocentric carries the genes *Q*, causing speltoid suppression, and b_1 causing awning; the arm of 5*B* carries the gene p_{5B}, causing the suppression of homœologous pairing; while the arm of 5*D* carries the prime factor for spring habit of growth. The characteristics associated with these genes, or their alleles, are now shown to be determined by equivalent arms of homœologous chromosomes. The acquisition of similar information about the arm relationships of the chromosomes of other homœologous groups would clearly provide a useful extension in the understanding of the genetic structure of wheat.

The aspect of this first investigation, however, that may offer the most promise for further work is the observation of differential pairing between the homœologues examined. Thus, when chromosomes 5*B* and 5*D* were simultaneously marked they paired together, usually as a rod bivalent, in about 50 per cent of cells. By contrast, when chromosomes 5*A* and 5*B* were simultaneously marked they paired together comparatively rarely, in only about 5 per cent of cells, and then often as a triradial trivalent which also incorporated a complete chromosome (Fig. 1*d*). These distinctive behaviours indicate a closer relationship between chromosomes 5*B* and 5*D* than between 5*A* and 5*B*, which may imply relatively greater evolutionary divergence in detailed structure and possibly in gene content between some homœologues than others. The extension of evidence of this kind to other homœologous groups, and its quantitative evaluation, should permit a reassessment of the evolutionary adjustment of *T. aestivum* to its polyploid status.

This first description of a technique for the cytological evaluation of chromosome homœology has outlined the possibilities made available in *T. aestivum*. Clearly the technique is feasible and offers considerable opportunities for the further genetic and cytogenetic investigation of the species; but its use need not be confined to intra-specific examinations. Provided that, in alien chromosome addition lines, one wheat and one alien chromosome can be simultaneously marked, the determination of the precise relationships between *Triticum* chromosomes and those of the alien species becomes possible through the suppression of the 5*B* effect by the *A. speltoides* genotype. Knowledge of these relationships would not only be of considerable interest in evolutionary investigations of the wheat group but might assist in shaping programmes for the improvement of wheat by the introduction of alien genetic variation.

MITOCHONDRIAL MORPHOGENESIS

By Dr. O. A. SCHJEIDE, R. G. McCANDLESS and R. J. MUNN

Laboratory of Nuclear Medicine and Radiation Biology, Department of Biophysics and Nuclear Medicine,
School of Medicine, University of California, Los Angeles

ALTHOUGH mitochondrial morphogenesis has interested many workers in cell biology, including Roullier[1], Faucett[2], Hoffman and Grigg[3], Green[4], Ross[5], Kilarski[6], McAlear[7], Luck[8], Robertson[9] and, more recently, Berger and Sjostrand[10], no such compelling evidence has been forthcoming that the presentation of still another perspective on this complicated problem is precluded.

In a series of earlier publications[11–13] we described a sequence of morphological steps which seem to characterize the assembly of 'mitochondria-like organelles'. These bodies are formed in the follicular cells surrounding the early oocytes of the hen. They are of about the same size as conventional mitochondria (about $0{\cdot}5\mu \times 2{\cdot}0\mu$). They possess a double external envelope with membranes of about 50 Å each (the dimensions of the membranes in conventional mitochondria is also about 50 Å) and what appear to be rudimentary cristæ (Fig. 1). They are synthesized in large numbers at the surfaces of the follicular cells and bud into the intercellular spaces whence they pass into the oocyte. Here they appear to participate in the organization of yolk (at least they are present in groups within the developing yolk granules), an association that is fulfilled by conventional-appearing mitochondria in the oocyte of the frog[11] and the turtle. It is not known if they contain succinic dehydrogenase or other enzymes associated with the Krebs cycle.

The earliest feature which has been definitely linked with their morphogenesis is the swelling of a vesicle (adjacent to the plasma membrane, suggesting that it has newly entered the cell) and the elaboration from this vesicle of a number of sub-vesicles which eventually spread about its entire inside surface. These sub-vesicles then stand out more darkly (in osmium-fixed material) and while in this state elaborate 'micro-vesicles' about their surfaces which fuse or elaborate further to form the two unit membranes of the envelope of the 'mitochondrion-like organelle' and also the rudimentary cristæ which are spaced about one sub-vesicle apart[13].

We feel we should be remiss if we did not at this point give some indication of our ideas regarding the origin and the nature of the vesicle that serves as a precursor for the formation of this organelle.

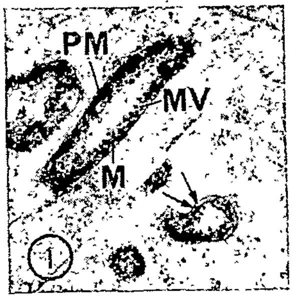
Our hypothesis is that the vesicle, or at least some of the material in it, may have originally arisen in the nucleus. Particularly in the oocyte, the nuclear membrane is heavily studded with so-called 'annular pores'. In the early chicken oocyte these 'pores' are, however, not wide open holes. An electron-dense granule appears to be firmly fixed in the centres of most of these[14] and it has been found in *Drosophila* that the magnitude of the potential across the nuclear membrane is independent of the number of 'pores'[15].

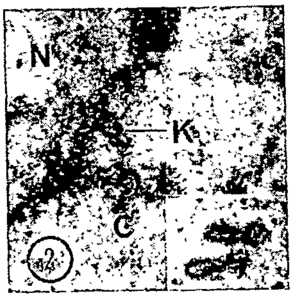
One way in which larger units appear to traverse these 'pores' is by reduction in size and in the case of vesicles by reassembly of micro- to sub- to 'mature' vesicles on the cytoplasmic side of the 'pore' (Fig. 2). The 'mature' vesicles very closely resemble the 'kinetosomes' of unicellular organisms. Although in *Paramecium* their origin has not been shown, Ehret and De Haller[16] and others have indicated that they appear to be involved in formation of cilia. They further point to their presence in certain vacuolated mitochondria of this organism[16]. Close inspection of the vesicles both in *Paramecium* and the oocyte of the hen (Fig. 2) reveal that they are bounded by single 'membranes' with bristled surfaces and that, at least in some cases, they contain centrally located rods or granules. Although they vary considerably in size and shape, the mature vesicles, when spherical, measure about 1500–2000 Å in diameter. They possess an inherent density which is characteristic of nucleic acid. Their failure to bleach on application of periodic acid and silver methenamine further attests to such a character. They (or vesicles resembling them) travel freely from cell to cell, going through the aforementioned process of dissolution and reassembly in order to traverse the two plasma membranes. Often, very similar appearing vesicles (commonly referred to as pinocytotic- or absorption-vesicles) form by a process of simple invagination of the plasma membrane. Our view is that the latter may be essentially similar in nature to the vesicles derived directly from the nucleus—that at least some of their materials are products of the nucleus and that the vesicles, whatever their immediate origin, carry some sort of information or scheme of organization provided by the genetic centre and destined for different expressions in the cytoplasm.

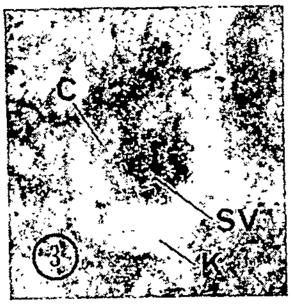
Some of the factors leading to our suspicion that the mitochondria-like organelles are formed in association with such nuclear precursors include: (*a*) a cohesive parcel of repeating organizational and/or informative units would appear to be a logical precursor for the synthesis of a radially organized structure such as a 'mitochondrion-like organelle'; (*b*) sub-vesicles and micro-vesicles are seen to contribute to—and elaborate from—the precursor vesicles, processes that are strongly reminiscent of the character of the 'kinetosomes' elaborated from the nuclear 'pores' (Fig. 2); (*c*) the precursor vesicles often present bristled exterior surfaces (micro-vesicles ?) relating them to 'kinetosomes'; (*d*) 'kinetosomes', including central granules, are observed within the fluid interiors of many mature 'mitochondria-like organelles'.

Although conversion of 'mitochondria-like organelles' into more conventional appearing mitochondria has been entertained by us, we are now of the opinion that this occurs rarely.

Observations have recently been made on mitochondria appearing in cells of early chicken embryos (18–24 h incubation) and on mitochondria of developing livers. As in the case of the 'mitochondria-like organelles' of the follicular cells, the ontogenesis of these bodies is intimately related to vesicles that exhibit at least two of the charac-







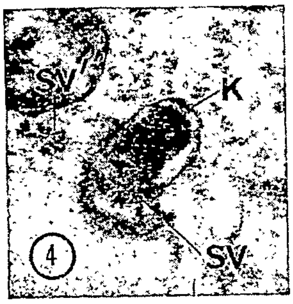


Fig. 1. Mitochondria-like organelles from an intercellular sinus between follicular cells. Note closely adherent plasma membrane (*PM*), double membraned mitochondrial envelope (*M*) and rudimentary cristæ (arrows). A rudimentary crista at point labelled (*M V*) consists of 2 micro-vesicles. (× *c*. 28,350)

Fig. 2. This vesicle (or kinetosome) (*K*) is being assembled on the cytoplasmic side of the nuclear pore from a number of smaller vesicles. Chicken oocyte: *N*, nucleus; *C*, cytoplasm. Inset shows fine structure of more fully differentiated vesicle. Note dense centre streaks. It is possible that the 'bristles' are actually the joined surfaces of micro-vesicles. (× *c*. 21,750)

Fig. 3. Cytoplasmic bud (*C*) with sub-vesicles (*SV*) projecting into lumen of expanded 'kinetosome' in chicken embryo cell. This is the earliest form in which a prospective mitochondria can be recognized at present. (× *c*. 39,000)

Fig. 4. 'Dense body' stage of mitochondrial morphogenesis in chicken embryo liver cell is depicted here. Sub-vesicles (*SV*) are present at base and to side (*SV'*). Observations indicate that some of sub-vesicles, elaborating from the sides of the kinetosome (*K*) and spilling out into the cytoplasm (*SV'*), are destined to form endoplasmic reticulum. No distinct membrane or envelope has formed about the bud. (× *c*. 28,350)

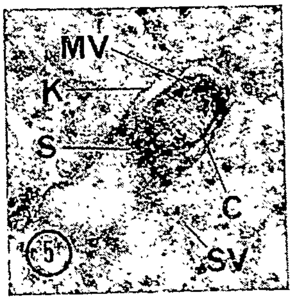
teristics of the above-mentioned 'kinetosomes', namely, bristled or 'fuzzy' limiting membranes and a propensity to convert to—and from—sub-vesicles and micro-vesicles.

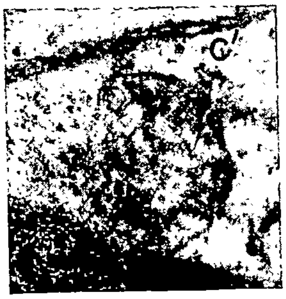
An initial event appears to be the expansion of a 'kinetosome' into a larger vesicle and the projection into it of a bud consisting of: (*a*) vesicular membrane; (*b*) sub-vesicles; (*c*) cytoplasm, including ribosomes (Fig. 3). This step in morphogenesis has also been observed by Berger[10], who makes the identification at the bases of the photoreceptors in the guppie where there is very little chance that it can be mistaken for another organelle. Thus, in contrast to the mode of formation of the rudimentary cristæ of the 'mitochondrion-like organelle', elaboration of an extensive system of cristæ apparently requires the presence of a substantial quantity of cytoplasmic material.

A later stage in the development of a mitochondrion is presumably represented by a bud that more nearly fills the lumen of the original vesicle (Fig. 4). Note that, except for the sub-vesicles at its base, it has become darker but retains a single limiting membrane. In some cases the bounding vesicle will dissolve away into smaller vesicles or the bud will break through it to lie in the ground substance of the cytoplasm. In this form it is recognizable as a 'dense body' long claimed by Roullier[1] to be a precursor form for mitochondria. It is, of course, possible that all mitochondria do not pass through this stage. However, elaboration of micro-vesicles is often, if not always, accompanied by a darkening in osmium-fixed tissues.

By the time the bud has become less dark again the beginning of cristæ formation appears to have taken place (Fig. 5). Some micro-vesicles can be discerned in it (arrows) and the large vesicle in which it lies has usually begun to dissociate into smaller vesicles some of which contribute to the newly forming endoplasmic reticulum in the case of chicken embryo and liver cells. Berger[10] indicates that the double membrane which constitutes the limiting envelope is formed by delamination from the original vesicle. That this is not so in all mitochondria described by us is indicated in Fig. 6. Here it appears that the limiting envelope of the mitochondrion, as well as its cristæ, is being formed by a fusion of—or elaboration from—micro-vesicles which have formed from the sub-vesicles of the bud. Further support for the existence and role of micro-vesicles in giving rise to cristæ is given in Fig. 7, which we think is an example of a mitochondrion which has for some reason failed to fuse—or keep fused—its micro-vesicles into cristæ (note that the organelle is bounded by a vesicular external envelope). A summary of proposed steps involved in morphogenesis of a mitochondrion in the tissues examined is given in Fig. 8.

It is, of course, precarious to select morphogenic steps from a series of photographs not sequentially related and in tissues where morphogenesis, though rapid, includes various organelles. The extent to which artefact may obtain is another consideration. However, the foregoing





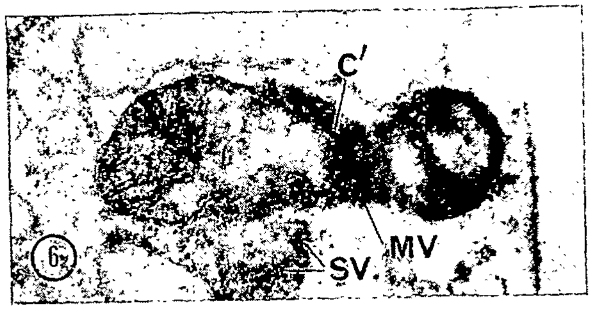


Fig. 5. In this later stage the prospective mitochondrion has become lighter again. The original vesicle (*K*) is dispersing into sub-vesicles (*SV*) (at several points) which do not appear to be contributing to the new mitochondrion. The bud is limited by a single membrane and is seen to contain sub-vesicles (*S*) and micro-vesicles (*M V*) which have contributed to the partial formation of at least one crista (*C*). The sub-vesicles at the lower right (*SV*) will form endoplasmic reticulum. The limiting membrane of the bud is thickened, suggesting that it may be doubling. (× *c*. 28,350)

Fig. 6. A nearly mature mitochondrion in chicken embryo cell suggesting that elaboration of limiting envelope as well as cristæ (*C'*) is by virtue of dissemination of micro-vesicles (*M V*) from sub-vesicles originating in cytoplasmic bud (Fig. 3). Although it is possible that these micro-vesicles are artefacts due to degeneration, osmotic—or other—factors, the general manner in which 'guidance' of detailed morphogenesis is accomplished is still indicated. Sub-vesicles labelled (*SV*) are from original vesicle. They are probably forming endoplasmic reticulum here since they are spaced the usual distance from the mitochondrion for such formation. (× *c*. 33,000)

Fig. 7. This body observed in a somatic cell from an early chicken embryo is thought to be a mitochondrion that has failed to assemble its cristæ (*C'*) from the micro-vesicles seen here or the cristæ of which have disassociated into such micro-vesicles. It is possible that it is a cistern of a Golgi apparatus, but such usually contain large sub-vesicles with well-defined centre granules. These, too, elaborate membranes by dissemination into micro-vesicles. (× *c*. 28,350)

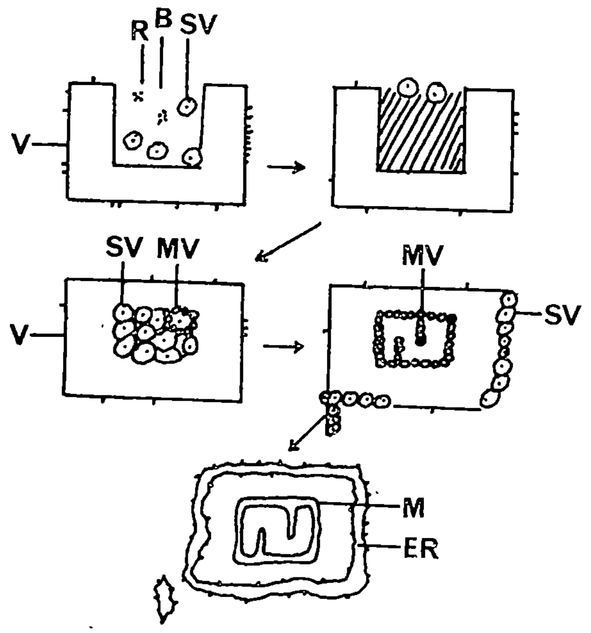

Fig. 8. Self-explanatory figure summarizing proposed morphogenic steps in mitochondrial development. *V*, vesicle; *R*, ribosomes; *B*, bud; *SV*, sub-vesicle; *MV*, micro-vesicle; *ER*, endoplasmic reticulum; *M*, mitochondrion

concepts are based on a large number of observations of different organelles; they develop a logical scheme of nuclear control over cytoplasmic differentiation and thus provide some new perspectives that may prove useful in this regard.

Although we have not attempted to demonstrate the existence of the micelles advocated by Sjostrand[17] as constituting the unit membranes of mitochondria, his concept is in complete accord with a scheme of morphogenesis by vesicular assignment. Some of the phenomena which may be associated with the transition of micro-vesicles to membrane sheets, including the micelles, may be revealed by future electron microscopy at higher resolution.

Before the wider concept of vesicle complexes originating in the nucleus, passing to the cytoplasm and there aiding in (or actually directing) the elaboration of mitochondria (or other organelles) can be unconditionally accepted, supporting data of an experimental nature must be forthcoming. It should also be shown to apply to other species[18,19].

EXERCISE OF MATING PREFERENCE BY A MERINO RAM

By R. H. HAYMAN

F. D. McMaster Field Station, C.S.I.R.O., Liverpool, New South Wales, Australia

MATING preference has long been postulated as one of the mechanisms concerned in the development of new species[1,2]. It does not appear, however, to have been observed in operation in wild-type or quasi-wild-type populations, although Thoday and Gibson[3] and Parker[4] have inferred that it occurred during the course of their experiments.

It is the purpose of this article to describe what appears to have been the exercise of mating preference by a Peppin Merino ram.

During the past twenty-five years a number of families of inbred Merinos have been developed on the C.S.I.R.O. McMaster Field Station at Badgery's Creek, New South Wales, Australia. Each family was founded by mating a single ram with a number of ewes. He was then mated to his own daughters and, provided that he survived, to his inbred female offspring from them. On his death or retirement for senility, his most inbred son replaced him as head of the flock, and the breeding programme was continued.

Two families of Peppin Merinos in particular, designated *B*323 and *B*464, were founded by sons of a sire known as *A*991 in 1942 and 1944 respectively. Our immediate concern is with the behaviour of two sires in these families, namely, *K*68 and *K*504, during the mating seasons of 1959, 1960 and 1961. Including *A*991 and *K*68 six generations of sires were used in the *B*323 family (Fig. 1), the pedigree of the sires themselves being shown in Fig. 2. The ancestry of *K*504 follows a similar pattern.

No selection was practised in these families except that each sire used was the most inbred young animal of mating age available at the particular time. All females born were introduced to the breeding flock at one and a half years of age and, provided that they remained physically sound, were retained therein as long as they lived. During mating each ram and his particular family of ewes were run together in a small paddock as a breeding group. The ram was marked on the brisket with coloured grease raddle, some of which he transferred to the rump of any ewe with which he mated. The flock was inspected daily, the ear-tag numbers of raddled ewes recorded, and fresh raddle applied to the brisket of the ram. On the seventeenth day the colour of the raddle was changed. The duration of each mating period was two clear œstrus cycles (34 days). Except at mating time all ewes on the Station were run together as a single flock. During lambing the flock was inspected daily, and new-born lambs were caught, ear-tagged and identified with their mothers.

Numbers of ewes in the two families were never great, and their reproductive efficiency declined as the level of inbreeding increased. Two young rams, *K*68 and *K*504, were brought in to head the flocks in 1959, by which time ewe numbers had become so low that recourse was had

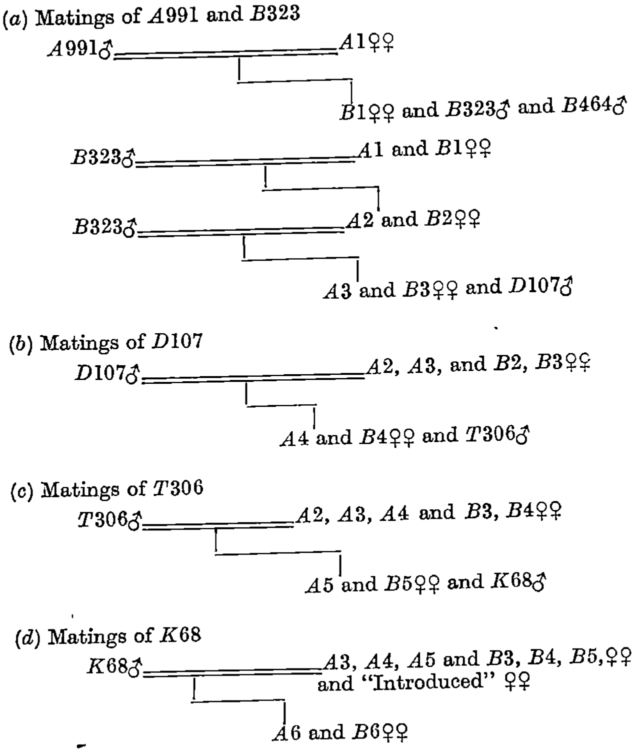

Fig. 1. Matings in the *B*323 family. *A*1, foundation ewes; *B*1, ewes by *A*991 ex *A*1 females; *A*2, ewes by *B*323 ex *A*1 females; *B*2, ewes by *B*323 ex *B*1 females; *A*3, ewes by *B*323 ex *A*2 females; *B*3, ewes by *B*323 ex *B*2 females; *A*4, ewes by *D*107 ex *A*2 and *A*3 females; *B*4, ewes by *D*107 ex *B*2 and *B*3 females; *A*5, ewes by *T*306 ex *A*2, *A*3 and *A*4 females; *B*5, ewes by *T*306 ex *B*3 and *B*4 females; *A*6, ewes by *K*68 ex *A*3, *A*4 and *A*5 females; *B*6, ewes by *K*68 ex *B*3, *B*4 and *B*5 females

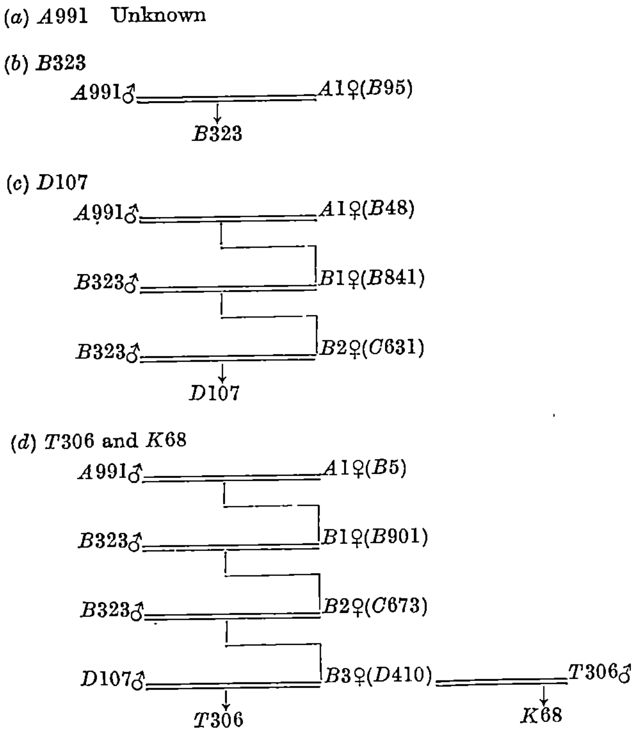

Fig. 2. Pedigrees of sires used in family *B*323

to the Peppin flock from which the foundation stock was originally purchased, and forty cast-for-age ewes were obtained. These were divided between the two families at random, twenty to each, and were described as the 'introduced' ewes to distinguish them from the inbred ewes already present.

The mating performance of each ram with both inbred and introduced mates for the seasons 1959, 1960 and 1961 are shown in Table 1.

Table 1. ANNUAL SUMMARY OF MATINGS IN THE *B*323 AND *B*464 FAMILIES DURING 1959–61 INCLUSIVE

Family	Sire	Year	Type of mate Inbred Mated	Not mated	Total	Introduced Mated	Not mated	Total
*B*323	*K*68	1959	22	0	22	5	14	19
	*K*68	1960	20	6	26	4	14	18
	*K*68	1961	24	3	27	4	14	18
	Totals, 3 years		66	9	75	13	42	55
*B*464	*K*504	1959	12	2	14	19	1	20
	*K*504	1960	11	4	15	20	0	20
	*K*504	1961	29	0	29	16	0	16
	Totals, 3 years		52	6	58	55	1	56

The results show no heterogeneity between years, and the behaviour of the two rams may be compared on their total number of matings over the three-year period.

The comparisons show that differences between the two sires in their matings with inbred ewes were not statistically significant ($\chi^2_1 = 0{\cdot}89$, $P < 0{\cdot}50 > 0{\cdot}30$), but that they differed greatly in their behaviour towards their introduced mates ($\chi^2_1 = 62{\cdot}454$, $P < 0{\cdot}001$). Thus *K*68 favoured his inbred mates above his introduced ones ($\chi^2_1 = 39{\cdot}462$, $P < 0{\cdot}001$), while *K*504 exhibited no preference ($\chi^2_1 = 3{\cdot}662$, $P < 0{\cdot}10 > 0{\cdot}05$).

Further, as shown by the results in Table 2, *K*68 consistently favoured a few females among his introduced mates, to the almost complete exclusion of the others.

Table 2. RECORDS OF MATINGS OF INTRODUCED EWES TO *K*68 DURING 1959–61 INCLUSIVE

Ewe No.	Year 1959	1960	1961
325	+	+	+
327	+	–	–
333	+	+	+
334	+	+	+
339	+	–	–
340	*	+	+

* Ewe No. 340 was in-lamb when purchased and was not able to mate for this reason.
+ Ewe mated by ram.
– Ewe not mated by ram.

The results strongly suggest that mating preference has been displayed by *K*68. Both rams were maidens at their first joining in 1959, and their behaviour could not have been conditioned by previous experience. The introduced ewes, being cast-for-age from a breeding flock, were known breeders themselves; they were divided between *K*68 and *K*504 at random, and it is most unlikely that those joined to *K*68 were in any way incapable of mating with him. It has already been stated that all ewes were run together as a single flock except at mating time, so there is no possibility that *K*68 avoided his introduced mates because they differed from the inbred ewes as the result of some artefact.

Three possible physiological reasons appear to exist for this mating phenomenon. *K*68 failed to recognize the usual olfactory signs of œstrus in the introduced ewes; he recognized them and avoided them; or the ewes avoided him. The last possibility is considered improbable as ewes in œstrus are known actively to seek the ram (ref. 5 and our own general observations). Of the two possibilities remaining, the first is considered most likely. Merino rams possess considerable libido and will occasionally try to mate ewes whether they are in œstrus or not; in fact, the raddling of ewes number

327 and 339 by $K68$ in 1959 could have been due to such attempts at mating, as neither ewe was recorded as either becoming pregnant or returning to service after 17 days. Because of this, it is concluded that he failed to recognize when the majority of the introduced ewes were in season.

If it is accepted that the mating preference exercised is under physiological control, it is necessary for the control itself to have a genetic basis, and that isolation and selection should have operated before the behaviour of $K68$ in relation to his inbred and introduced mates can be considered in relation to speciation. The common origin of the inbred families and the introduced ewes, together with the presence of a proportion of animals among the latter with which $K68$ could regularly mate (and from which he produced offspring), support the proposition that there is a genetic background. Isolation was provided by several generations of inbreeding in his relatively small one-sire family, such conditions being optimal for the increase of homozygous recessives. The phenomenon being considered is one in which, if the homozygous recessive is characterized by mating preference, natural selection against the heterozygote and homozygous dominant would be complete and rapid.

If $K68$'s mating preference was due to his having been a homozygous recessive for some physiological peculiarity which caused him to respond selectively to certain of the olfactory stimuli provided by ewes in œstrus, the fact that he mated with virtually all his related ewes indicates that one of his near ancestors was also homozygous.

For this explanation of the origin of the mating behaviour shown by $K68$ to be correct, three stages of mating behaviour should be evident in the $B323$ family records. During the first period they should be normal, during the second many ewes should appear to have aberrant records, and the third period should be characterized by a return to normal. A preliminary examination of the mating records for the entire family since its inception suggests that this course of events may have happened. Results of the detailed examination of the data will appear elsewhere.

IMPORTANCE FOR RADIO-PROTECTION OF THE REACTION OF CELLS TO SULPHYDRYL AND DISULPHIDE COMPOUNDS

By PROF. Z. M. BACQ

Laboratoire de Pathologie et Thérapeutique Générales, and Laboratoire de Recherches pour la Protection des Populations Civils, Université de Liège

AND

DR. PETER ALEXANDER

Chester Beatty Research Institute, Institute of Cancer Research, Royal Cancer Hospital, London, S.W.3

CHEMICAL protection by certain sulphydryl compounds and their disulphides against the lethal effects of ionizing radiations is a well-established phenomenon seen in nearly all biological systems. Evidence that radio-sensitivity can be increased by treatment with substances capable of reacting rapidly with SH groups under physiological conditions (called 'thioloprives' by Bacq[1,2]) is being found for a variety of cells[3] and some indications for sensitization have been found even with intact mammals[4]. Since experiments with isolated cell constituents such as proteins and nucleic acids as well as with viruses have shown that radiation damage of vital macromolecules can be protected against by SH compounds it seemed that protection *in vivo* could readily be accounted for by the fact that the SH protector diffuses into the cell and thereby raises the intracellular SH level[5]. Conversely, sensitization by thioloprives could be seen as the direct consequence of the reduction of the number of intracellular SH groups by direct chemical combination with reactive chemicals[6]. Recent investigations have shown that the actual situation in mammals (and certain types of isolated cells) is much more complex and that the SH protectors and the thioloprives may exert their action by shifting physiological processes within the cell. These agents exert a rather specific 'biochemical shock' which initiates a sequence of intracellular changes that then alter the radio-resistance of cells in either direction. It remains probable that the changes in radio-sensitivity are due to differences in the extent of protection offered by SH compounds to essential macromolecules—as demonstrated in model experiments[5]—but the level within the cell of SH and —S—S— protectors is determined *in vivo* by biological factors.

Intracellular concentration of protective agents. Pihl and Eldjarn[7] showed an impressive correlation between radio-protection in mice and the ability of some thirty —SH and —S—S— compounds to combine *in vitro* with proteins by a disulphide exchange reaction. As a consequence of this, and possibly other reactions, protective sulphydryl and disulphide compounds become bound to cellular components in tissues extremely rapidly. In rats injected with the —SH or S—S protectors one sees exactly the same pattern, as was found by Pihl and Eldjarn[7] *in vitro*, namely, that the protectors are bound to proteins in a few minutes. This rapid combination at the cellular level has been most clearly demonstrated for cysteamine and its disulphide, but related substances behave similarly. A number of investigations[8,9] have shown that the concentrations of non-protein —SH and —S—S— substances* within cells are not raised immediately after injection of SH protectors, but that at this time these substances are found bound to protein in the radio-sensitive organs. On standing, the non-protein SH levels rise in these tissues and part of this increase has been found to be due to the reappearance of the radio-protector itself (Fig. 1). In mice, Shapiro *et al.*[10] observed that ~ 20 min after injecting mercaptoethylguanidine (MEG) all this substance is no longer bound to protein, but that some of it is present in a free form. The physiological state of the cells must have undergone a profound change to make it possible for these reactive sulphydryl compounds (that is, MEG and cysteamine) to remain uncombined with proteins. Revesz and Bergstrand[11]

---

* The action of reductases and the occurrence of accidental oxidation make it technically very difficult to differentiate whether the non-protein bound protective agents are present in the —SH or —S—S form within the cell and for this reason they are expressed as the combined value.

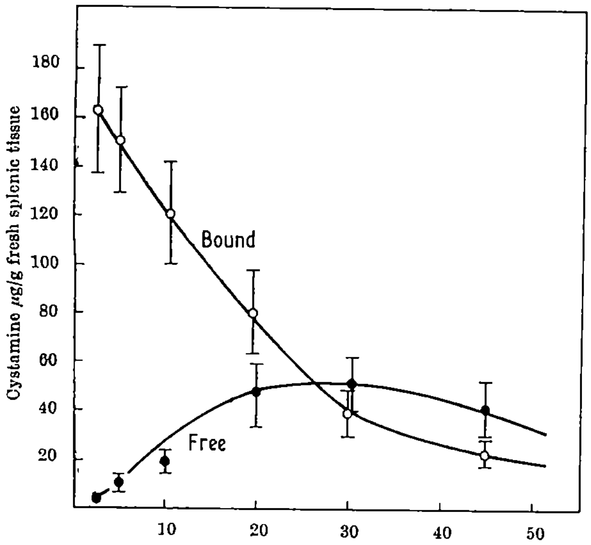

Fig. 1. Free and protein-bound cysteamine–cystamine in fresh splenic tissue of rats after intraperitoneal injection of 100 mg/kg of cystamine (drawn from results of Betz *et al.*, ref. 8)

find with ascites cells *in vitro* that the concentration of intracellular non-protein SH substances is considerably increased at 15 min after exposure to a solution of cysteamine. It seems likely that the protector will be bound rapidly even to isolated cells suspended in cysteamine-containing medium and the increase in intracellular free —SH substances may also here be partly indirect. The 'biochemical shock' produced by thioloprives may also cause a delayed change in the level of free intracellular —SH substances. Many of the thioloprives combine extremely rapidly under physiological conditions with —SH groups[1,2], yet changes in cellular —SH levels are only seen some time after injection[12].

If the protective action of the —SH and —S—S— substances relies on producing physiological changes in the cell, then optimum protection should not be seen immediately after irradiation. In mice, maximum protection with cysteamine and cystamine is found within 10 min of administration[13], but in rats Patt *et al.*[14] found cysteine to be fully effective 1 h after administration. Smoliar[15] showed that cysteamine is almost ineffective in rats 2 min after injection and that maximum protection against X-rays occurs 45 min post injection. The optimum period of protection does not coincide either with the time when binding of the protector to the proteins is at a maximum (which is very soon) or with the time when the protector exists free in the cell following a physiological release process (Fig. 1).

For protection against alkylating agents such as nitrogen mustards it has been generally observed[9,16,17] that the maximum effect is seen if the sulphydryl compounds are given a considerable time before the poison and the protection cannot therefore arise as a direct consequence of binding to proteins. The necessity for the long time interval also makes it most unlikely that the injected sulphydryl substances protect by themselves competing for the alkylating agent and it seems most plausible that the changes consequent on the 'biochemical shock' (possibly release of free SH substances) are also the actual cause of the protection against chemicals.

Nature of the 'biochemical shock'. The concept that the injection of the —SH and —S—S— protectors produce profound physiological alterations does not depend only on the finding that there are changes in the proteins of the cell which allows cysteamine (or its disulphide) and MEG to reappear and to remain unbound. Evidence for a 'biochemical shock' is also revealed by the observations that, within minutes after injection of cysteamine, ascorbic acid and other unidentified reducing substances are liberated in the plasma[18], glycogenolysis occurs in the liver[19] and the glutathione content falls in the liver and kidney[20]. Cystamine has an immediate and pronounced effect on the respiration of cells[21].

A series of observations by Neubert and Lehninger[22] may help in the elucidation of the mechanism by which the protective agents produce the 'biochemical shock'. Various —SH and —S—S— compounds induce a discharge or leakage from rat liver mitochondria of contraction factors which cause the mitochondria to undergo a peculiar type of swelling which is not reversed by the addition of adenosine triphosphate. There is a correlation between the ability of substances: (1) to bring about this change in mitochondria; (2) to protect against radiation *in vivo*; (3) to undergo disulphide exchange (for example, cysteine, cysteamine and glutathione are active while penicillamine, ergothionine and mercaptoethanol are inactive). Mercaptoethanol is particularly interesting since this substance protects bacteriophage and isolated nucleoprotein—presumably by a direct physicochemical mechanism[5]—but is quite inactive as a protector in mammals and its disulphide reactivity as well as its action on mitochondria is also poor.

As a result of disulphide exchange, the activity of intracellular enzymes will be affected and bound —SH compounds will be set free. This, however, can only be a first step since the delayed release of protein-bound protective agents is indicative of extensive alterations of some proteins in the cell. One might speculate about changes following disulphide exchange in the activity of glutathione reductase and peroxidase which displace the —S.S→SH equilibria and increase the concentration of —SH groups in the cell available for physico-chemical methods of protection. Inhibition of enzymes by thioloprives could act in the opposite direction and via metabolic processes decrease the concentration of —SH groups available for protection. The place at which the injected protectors and sensitizers act in the cell need not therefore be the same as the site of the radiation induced primary lesion which initiates the processes that lead to the death of the cell. It is also quite possible that some treatments which change the radio-sensitivity of mammals and which do not initially involve reactions with —SH or —S—S— groups may bring about changes in intracellular —SH levels. In this way quite unrelated compounds may alter radio-sensitivity through a common pathway. The failure[23] of animals which have received repeated injections of cysteine over a period of weeks to be protected by a further dose given before irradiation can be explained as inability (possibly by exhaustion) to respond in the normal way to the insult of an injection of a massive dose of —SH or —S—S— substance.

On general biochemical grounds it is obvious that the —SH ⇌ S—S— equilibrium (free and protein-bound) in the vegetative cell is a carefully balanced system. If disturbed by the introduction of extraneous —SH and —S—S— substances the physiologically active cell is bound to respond to this change. In retrospect it is clear that a direct extrapolation to the whole mammal of mechanisms clearly identified in less complex systems is illogical. We[24] still incline to the view that the mechanism of protection of mammals at the molecular level involves interaction of SH groups with radicals and that processes such as instantaneous repair of the primary lesion by hydrogen transfer[5] are ultimately responsible for the observed increase in radio-resistance. The —SH groups responsible for such reactions are, however, not necessarily directly related to the protective agent that has been injected. The possibility that the 'biochemical shock' produced by the protective agents raises the post-irradiation repair capacity of the cell cannot be excluded, but the 'universality' of chemical protection makes this mechanism rather unlikely. Before any of the suggestions about the mechanism of protection at the molecular level can be considered as more than speculation, much more basic information must be obtained about the biochemical changes which follow on the intoxication of mammals with —SH and —S—S— substances.

LIPID DEPOSITION IN INTERCELLULAR SPACE

By Prof. FLORA MURRAY SCOTT

Department of Botany and Plant Biochemistry, Los Angeles, California

THE physiological anatomy of wound healing by suberization and cork formation was investigated comprehensively by Haberlandt[1]. The wound hormone postulated as the stimulating agent has been isolated, analysed and tested physiologically in recent years[2–4]. The experimental work of Priestley indicated that causal factors in cork formation include the presence of oxygen in the air and a supply of food material[5]. In higher plants the development of intercellular spaces and deposition of lipid material on the limiting cell walls appear to confirm this theory. The breaking of plasmodesmata during cell expansion is virtually a wounding of the protoplast. Air enters the intercellular space, and apparently simultaneously lipid deposition begins on the wounded cell. The lipid is extruded presumably through the plasmodesmata. The elaboration of traumatin and of lipid is presumably the first reaction of the wounded protoplast and is followed by the microscopically visible deposition of lipid.

In the past 30 years the structure and composition of cellulose, the principal component of the plant cell wall, have been intensively investigated by light and electron microscopic techniques, and by chemical and physical methods[6–10]. Chemical analyses of other wall components, the cutin and the suberin of epidermis and cork respectively, also of lignin and the non-cellulosic polysaccharides, indicate variation in different species. In the present article, the deposition of a non-cellulosic lipid layer on the cell walls limiting the intercellular spaces and extending therefrom to the walls of adjoining idioblasts is discussed.

The term 'internal suberization' was first used to connote a non-cellulosic lipid layer which lines all intercellular spaces in the leaf of the orange, *Citrus sinensis*[11]. This layer resembles cutin and suberin in its microchemical behaviour in testing for cellulose by treatment with $I_2KI-H_2SO_4$. The cellulose swells, turns blue and eventually disappears, but the suberin remains intact, or fragmented *in situ* if in young tissue. The reaction may be slowed or stopped for recording on 'Kodachrome' by irrigation of the section with glycerin. Since later work showed that all intercellular spaces in stem and root apices and in other meristematic tissues are also lined with a pellicle similar in microchemical reaction to that seen in mature leaves, the term lipid layer appears preferable to suberin layer[12].

In the higher plant the meristematic cells of shoot and root tip, of leaf, flower and fruit primordia, are polyhedral and approximately isodiametric. All cell faces are pitted ubiquitously. During growth and cell expansion the cell corners round off, certain of the marginal plasmodesmata are broken and these broken ends contract into the cell wall. The first intercellular spaces, minute but visible under the light microscope because air-filled, occur within about 20 microns of stem and root apices[12].

The cell walls limiting these intercellular spaces are already lined with a thin film of non-cellulosic lipid material. As differentiation of parenchyma such as cortex and pith proceeds, the polyhedral cells become spherical, ellipsoidal or cylindrical[13]. The intercellular space forms a continuum, a network throughout the entire axis, also through leaves, flowers and fruits. On the end walls of the elongate cells, the pit pattern remains as in the meristematic cells, the pits small and ubiquitous. In contrast, on the lateral walls, the pits are larger in diameter, fewer in number and are aligned in vertical series. Through them the plasmodesmata maintain connexion with the surrounding cells, 5–7 in number. During growth the lipid pellicle either thickens to a well-defined layer around the now conspicuous intercellular spaces, or it may remain tenuous. The thickness varies in different species, is conspicuous in xerophytes, while in the hydrophytes examined it is thin as in meristematic tissues.

It seems probable that the long-lasting quality of flowers may depend on the thickness of the lipid layer in the intercellular spaces. In the petals of *Camellia* sp., in orchids such as *Cypripedium* sp., and *Cymbidium* sp., also in the spathe of *Anthurium* sp., the lipid layer is thick as in xerophytic leaves. In contrast, in *Primula* sp., where the flowers, cut or uncut, last for a day or less, the pellicle is tenuous as in the hydrophytes.

It is generally stated in text-books that intercellular spaces are absent in the vascular tissues of the higher plants. In *Ricinus communis*, however, in living material, minute air-filled spaces occur around differentiating spiral vessels[14]. These spaces are lined with lipid pellicles visible under light and electron microscopes. In vessels which have reached their full diameter, but in which the walls are not yet lignified, the cylindrical cellulose wall and the spiral thickening disintegrate during microchemical treatment with $I_2KI-H_2SO_4$. A cylinder, or in sectioned material a ring, remains which is marked by projecting ridges, equal in number to the intercellular spaces between the surrounding cells. This lipid cylinder is evidently formed during vessel differentiation by the lateral extension of lipid pellicle from the intercellular spaces along the plane of the middle lamella.

The endodermis has long been recognized by the suberization and, generally also, the lignification of the Casparian strip. Lipid-lined intercellular spaces occur between the inner zone of the cortex and the outer face

Phylogeny and Form in the Plant Kingdom

H. J. DITTMER, Professor of Botany, University of New Mexico

After an introduction to taxonomy, the book proceeds systematically from blue-green algae to angiosperms. The treatment of lower plants is unusually full, and there are special chapters on ecology of the algae, the origin of vascular plants, and problems of plant evolution. Besides questions and references at chapter ends, there is a large glossary.

Biology and Its Relation to Mankind

(3rd Edition)

A. M. WINCHESTER, Professor of Biology, Colorado State College, Greeley

For this third edition, a new double-column format has been combined with page-by-page revision to heighten clarity of presentation. Descriptions of photosynthesis, meiosis, genetics, etc., have been completely re-done, and many chapters are reorganised, with added illustrations. The new format allows superior reproduction of the nearly five hundred illustrations, always a strong feature of the author's books.

(*July* 1964), 450 *illus.*, 5¾ × 9½, 648 *pages*, 66*s*. *net*

Quantum Mechanics

G. L. TRIGG, Brookhaven National Laboratory, Upton, New York

It accomplishes its two primary purposes: first, to show how soundly the theoretical structure is based on reasonable assumptions about the physical nature of the universe and our modes of observing it; and second, to introduce some of the more involved and elaborate computational as well as conceptual aspects of the theory, including the complications of relativity. This book is written for a full year course at the graduate level.

Illus., 6 × 9, 400 *pages*, 76*s*. *net*

Principles of Random Walk

F. SPITZER, Professor, Dept. of Mathematics, Cornell University, New York

This book, the only one of its kind, is concerned with the mathematical theories underlying the principles of random walk, on the integer lattice points of d-dimensional Euclidean space. The author's object is to connect random walk with potential theory, and, to a lesser extent, with boundary theory. By confining himself to the case of random walk, he gives a clear account of these matters within a simple framework.

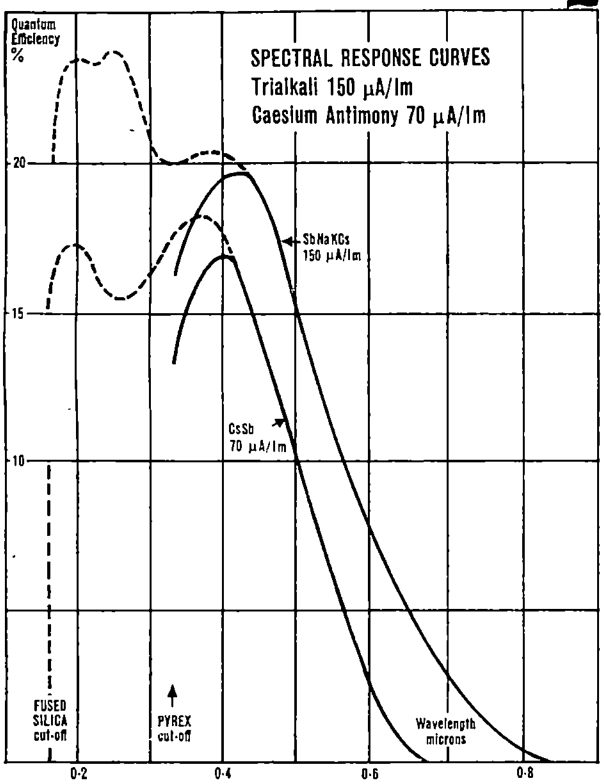
PHOTOMULTIPLIERS 9558B AND 9558Q



The 9558 has an end window trialkali cathode giving high response at wavelengths up to 0.8 microns, as shown in the curve. The high quantum efficiency at wavelengths between 0.6 and 0.8 microns, compared with other types of cathode, makes the tube of great interest to spectroscopists and astronomers and workers in the laser field. The dark current from the trialkali cathode is very low and is around 500 electrons per second per cm^2 (at room temperature). Characteristics of the 9558 are given below:

Dimensions Cathode diameter 44 mm min. Seated height 140 ± 3 mm.
Bulb diameter 51 5 mm max.
Photocathode Trialkali—Caesium Sodium Potassium Antimony.
Window 9558B—Pyrex (0.3—0.85µ) 9558Q—Fused Silica (0.16—0.85µ).
Dynodes 11 Venetian Blind, SbCs coated.
Photosensitivity 140 µA/lm typical 100 µA/lm min.
Voltage for 200 A/lm* 2000V max. 1450V typical
Dark current at 200 A/lm† 10^{-8} A max. 2 x 10^{-9} A typical

*Measured with 2870°K Tungsten lamp; 150V C–D1, uniform dynode chain thereafter. 200 A/lm corresponds to a gain of circa 1.5 x 10^6 in a median tube.
†At 20°C, measured after one hour operation in dark.

COPLAND-DAVIES ELECTRODE

Stainless steel polished wire forms a self-retaining clip, 2 cm in length, by which subdermal connections are simply, firmly and painlessly made, for recording heart rate and myography during exercise or encephalography. Price per set of 3 with flexible connection wires 32/6.

Pitman

PHYSICS IN BOTANY

J. A. Richardson, M.Sc., Ph.D., A.Inst.P.

Spectacular advances have been made in biological studies through the adoption of extraneous scientific skills. The aim of this book is to illustrate the wide range of botanical problems where, through the application of the techniques and ideas of modern physics, a fuller understanding of the functioning of the living plant has been achieved. Comprehensive in scope yet lucidly written, "Physics in Botany" will be of great value to 'A' level students and undergraduates.

MANSFIELD OIL-GAS PLANT FOR LABORATORIES' GAS SUPPLY

• *Reliable* • *Simple to Operate* • *Safe*

Provides a gas supply at a constant calorific value of 1,350 B.T.U.'s per cu. ft. produced from Light Diesel Oil, Gas Oil, Paraffin, or other suitable oils available at low cost.

Enables the efficient use of a full range of modern gas burning appliances in any part of the world. Ideal for glass blowing and gives perfect oxidizing or reducing flames with ordinary atmospheric burners.

For full particulars send details of estimated number of burners to be used.

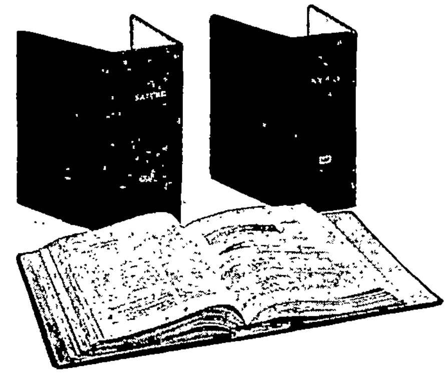
THE EASIBINDER *will* **BIND**
your **Trade** *and* **Technical Journals**



Binders for Nature hold 1 Vol. and Index (13 Issues)
Gold blocked with title and year, Price 16/- post paid
(please specify year when ordering)

The EASIBINDER is used by Librarians of Government, Industrial and Research Establishments in all parts of the British Commonwealth.

Designed for both permanent and temporary binding of technical journals, it facilitates the formation of a reference library of current journals with no danger of lost or soiled copies.

The journals are easily inserted with steel wires (supplied with the binders) and can be removed and replaced at any time. By means of a special device the binder is just as useful when only partly filled as it is when completely filled.

Easibinders can be supplied for all journals, gold blocked with any title, and in addition, the year of publication.

Please write for full particulars of the Easibind device.

'MICHROME' STAINS AND REAGENTS FOR MICROSCOPY, ETC.

Over 3,000 available, including:

Acetylated Sudan black. Acridine orange. Aesculin, FS. Alcian blue. Amido black 10B. Amylases. Aurantia. Astrazone red. Auramine. Azo violet. Azur, A, B, C, etc. Carmine. Canada balsam. Celestin blue. Celloidin flakes. Chlorantine fast red. Chlorantine fast green. Chlorazol fast pink. Chlorazol paper brown. Chromosome red. Chromotrope F4B, Chromotrope 2R. Coriphosphine O. Cresyl fast violet. Crocein scarlet. Crystal violet. Cyanin. Cyanol FF. Cytase. Cyanol blue. Dahlia. Dark room red. Deltapurpurin. Deoxyribonucleic acid. Deoxyribonuclease. Dichloro Fluorescein.

Diazo blue salt B. Dextrose, bact. Diazin green. Diazonium salts. Digitonin. Dicyanin. Di-iodofluorescein. Dimethyl yellow. Dinitroresorcinol. Disulphine blue. Echt gelb tusch. Elastin stains. Emicellulase. Erie garnet. Eriochrome black T. Erythrosin. p-Ethoxychrysoidin. Euchrysin. Fast black salts. Fast blue salts. Fast red salts. Fat red 7B. Fettrot. Field's stain. Fluorescein. Fuchsin acid. Fuchsin basic. Fuchsin neutral. Gallamine blue. Gallein. Gallocyanin. Garnet GBC salt. Giemsa stain. Glucose phosphates. Gold chloride. H-Acid.

Hansa yellow. Hofmann's violet. Haematein. Haematoxylin. Hickson's purple. Indigo. Haplos. Indigocarmine. Indophenol. Inositol, bact. Isamine blue. Janus black. JSB stain. Jenner stain. KH Stains (for keratin). Lacmoid. Leishman stain. L-Leucyl-b-naphthylamine HCl. Lignin pink. Lipase. Lipid crimson. Luxol fast blue. Malt extract. Manchester blue. Mannitol, bact. Marshall red. Maxilon blue RL. Mercury orange. Methyl green OO. Methyl orange. Methyl red. Methylene green. Methylene violet. MF/4 stain (for keratin). *MMT.* Naphthalene violet.

Nuclear fast red salts B & R. Naphthazurin. Naphthols, AS, etc. Naphthol violet. Naphthyl acetate. Naphthyl phosphate. Neutral red. Neutral violet. New blue R. Neococcine. Neotetrazolium chloride. New fuchsin. Nile Blue. Nitrazine yellow. Nitrotetrazolium blue. Oil blue N. Oil red O. Orcein. Panchromatic green. Papanicolaou stains. Pararosaniline. Paraldehyde fuchsin. Patent blue V. Pectin. Phloxine. Phthalocyanin. Pinacryptol yellow. Polyvinyl alcohol. Ponceau S. Propyl red. Pyoktannin. Pyronin Y(G). Rapid filter blue. Ribonucleic acid. Ribonuclease.

RSR reagent. Rosaniline sulphate. Rose bengal. Rosolic acid. Salicin, bact. Shorr's stain. Sienna orange. Sodium thioglycollate. Sodium taurocholate. Sodium deoxycholate. Sudan black. Sudan green. Sudan violet. Sun yellow G. Tetrazolium blue. Tetrachlorofluorescein. Tetrazolium violet. Tetranitrotetrazolium blue. Titan yellow. Toepfer's reagent. Toluidine blue. Trypaflavin. Trypan blue. Trypsin. Turquoise blue. Urease. Variamine blue. Victoria blue. Vital red. Waterwax. Wool green S. Wright's stain. p-Xylenol blue. Yeast extract, bact.

Other 'Michrome' specialities include:

For Histology, etc.

RHODANILE BLUE, an entirely new type of basic dye recently discovered in the Michrome Laboratories. Rhodanile blue is a one-dye differential stain with unusual properties. Maximum Resolution
Minimum Effort

This new instrument is based on the well-known EM6. Extensive redesign has made it particularly suitable for biological work, the object being to combine high performance on transmission specimens with extreme simplicity of operation.

The electron optics are based on a new high performance objective lens. Particular attention has been paid to ease of operation. The number of controls—the panels are shown above—has been reduced to less than half those on any other high performance electron microscope. The specimen holder can accommodate three samples at one loading to speed the rate of examination; and specimen contamination has been drastically reduced.

The accelerating voltage can be selected from the range 30, 40, 50, 60, 80 Kv as desired. Magnification, ranging from X1000-X250000, is controlled by a single switch.

In spite of the unprecedented simplicity of control, this instrument has consistently achieved a resolution of 5 angstrom units.

of the endodermis. Minute intercellular spaces are also seen along the inner face of the endodermis and the adjacent vascular parenchyma. Suberization of the Casparian strip probably begins at the time when the air enters the abundant intercellular spaces formed during the expansion of the cortical and other cells. Suberization of the strip frequently more or less blocks the pits in the radial walls of the endodermal cells, as is seen under the electron microscope[15]. To what extent this suberization interferes with intercellular transport in the young root is not known.

The ovary of the dicotyledons, in its early stage of development, consists of a papilla of meristematic cells in plasmodesmatal connexion. During growth, as seen, for example, in *Ricinus*, differential expansion occurs in the inner wall of the carpel and the outer integument of the seed. The differentiated epidermal walls of the carpel and the seed become separated by an air space and the cutinized surfaces of both are already stainable with sudan 3.

The embryo of the higher plant is at first surrounded by nucellus and endosperm. When plasmodesmatal connexions between embryo and nutritive tissues eventually break, the epidermis of cotyledons, radicle and plumule becomes cutinized. It is probable that, by this time, a film of air surrounds the embryo. The cutinization of the epidermis is retained in the primary root[16].

In the seed coat of the xerophyte, palo verde (*Cercidium macrocarpa*, family Leguminosae), the epidermal cells, palisade-like in outline, are enveloped in a lipid sheath[17]. In the same seed, the mucilage zone of the inner integument consists of stellate cells. In the living material, examined at various stages of growth, no air has been observed in the intercellular spaces at any time. The spaces between the radiating cell arms are filled with an amorphous mass of mucilage. Nevertheless, in these spaces a thin pellicle of lipid material occurs which parallels the cellulosic pitted arms at a distance of a few μ. It is considered probable that, in the mucilage mass, a gradient in oxygen content exists which stimulates the localized deposition of the lipid layer.

Intercellular spaces, lipid-lined, are ubiquitous in the mesocarp of the avocado, *Persea americana*, fruit. They appear between parenchymatous cells, and around the characteristic oil idioblasts[18]. Differentiation of the oil idioblast includes the thickening and suberization of the pitted wall and the impregnation of the delicate cellulosic oil sac membrane with a certain amount of lipid material. The penetration of aqueous stains such as neutral red, Janus green, thionin, and anilin blue into the developing idioblasts is retarded at an early stage of growth and is eventually inhibited in the ripe fruit. To what extent, if at all, the suberization of the pitted idioblast wall affects the transport of precursor reserve materials through the plasmodesmata into the oil sac is unknown.

Under the electron microscope, the layers of suberin isolated from *Cercidium*, *Ricinus* and *Persea* are similar in appearance. They resemble in texture a very fine, porous, artificial rubber or plastic sponge. With the isolation techniques used at present, clearing and ultrasonic treatment, these layers vary in thickness in younger and older tissues but are indistinguishable morphologically[14,17,18].

The deposition of lipid on cell walls bordering intercellular spaces appears to be similar to the reaction of the epidermis on wounding, for example, in the fruit of the orange, *Citrus sinensis*[19]. The epidermis of *Citrus* fruits of various species consists of tabular cells, polygonal in outline, interrupted by stomata and sub-epidermal oil glands. In young fruits, 1–3 cm in length, the epidermis may be strained to cracking point and minute slits torn between adjacent cells. The plasmodesmata are broken at least temporarily. The wounds appear to be healed simultaneously by cutin deposition, indicated by irregular thickenings in the radial cell walls, which are stainable with sudan 3. These occur occasionally near stomata or oil glands, but more generally between unspecialized epidermal cells. The inherent weakness of the epidermis of *Citrus* is a factor in the pathology of water spot. In the ripe fruit, cracks are caused presumably by physiological variations of internal pressure, and at this time the epidermal cells are no longer able to keep pace with the elaboration of cutin necessary to heal the cracks. The ensheathment of the epidermal cells of the seed coat of *Cercidium* may originate in a similar way by the healing of epidermal cracks which develop during seed growth.

The causal factors of the intracellular deposition of lipid material, cutin or suberin, in calcium oxalate crystal idioblasts appear to differ from those hitherto discussed in this article. Calcium oxalate crystals develop in living cells and the form of the crystal, solitary or druse, depends on the pH of the cell[20]. The crystals are enclosed in a cellulose sheath. In mature idioblasts the crystals may fill almost the entire cell cavity, while the protoplasm with nucleus and organelles, although now parietal in position, appears normal as seen under the light microscope. The cellulose sheath, however, is now impregnated with lipid, and a similar layer lines the inner surface of the idioblast. At no stage in the development of these idioblasts has air been observed within the cell cavity[21].

In conclusion, lipid distribution on the cell walls which bound the intercellular space system of the higher plant may be considered to be a wound reaction. The wounding of the protoplast occurs during cell expansion when the interconnecting plasmodesmata are broken. The protoplast reacts by elaboration of wound hormones and lipid precursors. The lipid layer deposited on the cell wall is the first microscopically visible reaction. The presence of air is, in general, essential for the deposition of lipid. During growth, the lipid layer thickens, and in many cases may extend in any direction from the initial intercellular space along the plane of the middle lamella of adjacent cells. The factors which control this extension are unknown at present.

The deposition of lipid in mucilage-filled intercellular spaces of the inner integument of the seed of *Cercidium* is interpreted, at present, by postulating an oxygen gradient in the amorphous mucilage mass which is extruded from the many armed cells of the tissue.

The intracellular cutinization or suberization of calcium oxalate crystal idioblasts apparently follows a pattern different from that in the intercellular spaces since the presence of air has not been observed in any of the material examined.

It is expected that, in the near future, the techniques of ultra-thin sectioning will clarify some of the innumerable problems of lipid deposition on, and in, the cell wall.

ISOLATION FROM SPINACH CHLOROPLASTS OF PARTICLES CONTAINING DIFFERENT PROPORTIONS OF CHLOROPHYLL *a* AND CHLOROPHYLL *b* AND THEIR POSSIBLE ROLE IN THE LIGHT REACTIONS OF PHOTOSYNTHESIS

By Dr. N. K. BOARDMAN and Dr. JAN M. ANDERSON
C.S.I.R.O. Division of Plant Industry, Canberra, Australia

EVIDENCE in favour of the concept of two distinct primary photochemical reactions in the process of photosynthesis in the green plant has been reviewed recently[1]. These primary reactions are thought to be driven by light absorbed by two pigment systems which have been denoted system 1 and system 2. System 2 absorbs more light of the shorter wave-lengths than does system 1, but the pigment composition of the two systems is unknown[2]. There is evidence from spectrophotometric investigations to support the hypothesis that light absorbed by system 1 causes the reduction of NADP and the oxidation of a cytochrome, while light absorbed by system 2 causes the reduction of the cytochrome and the oxidation of water to oxygen. The products of the light phase of photosynthesis, $NADPH_2$ ATP and O_2 result from the co-operation of the two systems.

The photoreduction of NADP by isolated chloroplasts coupled to oxygen evolution is inhibited by 3-(*p*-chlorophenyl)-1 : 1-dimethyl urea (CMU)[3,4], which is thought to act on system 2, and prevent the reduction of the cytochrome[1]. The inhibition of NADP reduction can be overcome by the addition of the electron donor, sodium ascorbate plus an indophenol dye, suggesting that reduction under these conditions results from light absorbed solely by system 1.

The aim of the work reported in this communication was to fractionate the chlorophyll–protein complex of the spinach chloroplast in an attempt to obtain a physical separation of the two pigment systems.

Spinach chloroplasts, prepared in an isotonic sucrose medium, were fragmented by incubation at 0° in 0·05 M phosphate buffer, *p*H 7·2, containing 0·01 M potassium chloride and 0·5 per cent digitonin. The resulting chlorophyll-containing particles were separated by differential centrifugation. The first centrifugation was for 10 min at 1,000*g* and this was followed by centrifugations at 10,000*g* for 30 min, 50,000*g* for 30 min and 144,000*g* for 60 min. The pellet from each spin was resuspended in 0·05 M phosphate buffer, containing 0·01 M potassium chloride. The chlorophyll content of each fraction was determined by taking suitable aliquots, making them 80 per cent with respect to acetone, clarifying by centrifugation and analysing spectrophotometrically. The equations of Vernon[5] were used to calculate the contents of chlorophyll *a* and chlorophyll *b*. Each fraction was tested for the following photochemical activities: (1) reduction of *o*-chlorophenol-2,6-dichloroindophenol (TCIP); (2) reduction of NADP; (3) reduction of NADP with sodium ascorbate and TCIP as the electron donor couple.

Previously, Wessels[6] had reported that chlorophyll-containing fragments, prepared by incubation of spinach chloroplasts with digitonin, followed by centrifugation between 5,000*g* and 50,000*g* were capable of cyclic phosphorylation, and of NADP reduction if provided with a suitable electron donor.

Table 1. CHLOROPHYLL CONTENT OF FRACTIONS ISOLATED FROM SPINACH CHLOROPLASTS

Fraction	Chlorophyll content (μg)	$\frac{A663}{A647}$	$\frac{\text{Chl. } a}{\text{Chl. } b}$
Chloroplast suspension	3,120	2·31	3·0
1,000*g*	580	2·12	2·4
10,000*g*	1,374	2·14	2·5
50,000*g*	373	2·68	4·6
144,000*g*	259	2·91	6·2
144,000*g* supernatant	336	2·80	5·4

Table 2. PHOTOCHEMICAL ACTIVITIES OF FRACTIONS ISOLATED FROM SPINACH CHLOROPLASTS

Fraction	Rate of reduction (μmoles/mg chlorophyll/h) TCIP*	NADP†	NADP† (ascorbate plus TCIP as electron donor)
Chloroplasts in phosphate buffer	195	109	58
Chloroplasts in digitonin	92	13	35
1,000*g*	116	20	14
10,000*g*	56	14	12
50,000*g*	4	0	39
144,000*g*	0	0	117
144,000*g* supernatant	0	0	84

* The reaction mixtures contained (in 3 ml.) chloroplast fraction equivalent to 7 μg chlorophyll and (in μmoles) *tris*-HCl buffer *p*H 7·8, 40; sodium chloride, 70; TCIP, 0·06. The reaction rates were measured by the decreases in absorbancy at 620 mμ after illumination for 45 sec at 40,000 lux.

† The reaction mixtures contained (in 3 ml.) chloroplast fraction equivalent to 25 μg chlorophyll and (in μmoles) *tris*-HCl buffer *p*H 8·0, 40; sodium chloride, 70; magnesium chloride, 10; NADP, 0·6; and spinach PPNR sufficient to saturate the system. Where sodium ascorbate and TCIP were added, the amounts were (in μmoles) sodium ascorbate, 6·0; TCIP, 0·02. The reaction rates were measured by the increases in absorbancy at 340 mμ after an illumination time of 2 min at 40,000 lux.

The results of an experiment in which the incubation time in digitonin was 30 min are shown in Tables 1 and 2. A significant finding was the different proportions of chlorophyll *a* and chlorophyll *b* in the various fractions. The (0–1,000*g*) fraction (later designated 1,000*g* fraction) and (1,000*g*–10,000*g*) fraction (10,000*g* fraction) had lower chlorophyll *a*/chlorophyll *b* ratios than the chloroplasts whereas the (10,000*g*–50,000*g*) fraction (50,000*g* fraction), the (50,000*g*–144,000*g*) fraction (144,000*g* fraction), and the high-speed supernatant (144,000*g* supernatant) had higher ratios. The difference in the proportions of chlorophyll *a* to chlorophyll *b* between the 10,000*g* and 144,000*g* fractions was evident also from absorption curves of the fractions (Fig. 1). The *in vivo* absorption band of chlorophyll *b* at 650 mμ (ref. 7) was clearly visible in the 10,000*g* fraction. The main absorption maximum of the 10,000*g* fraction was shifted slightly to the blue (about 2 mμ) as compared with the 144,000*g* fraction.

A comparison of the figures in Table 2 for the photoreduction of NADP and TCIP by intact chloroplasts and chloroplasts treated with digitonin shows that there was a greater percentage loss in the rate of NADP reduction.

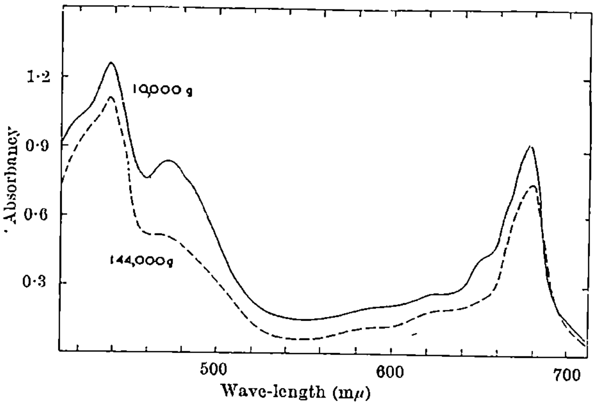

Fig. 1. Absorption spectra of fractions obtained from spinach chloroplasts by incubation with digitonin and differential centrifugation. —— 10,000*g* fraction; ---- 144,000*g* fraction

Table 3. EFFECT OF ADDING FERREDOXIN OR A CRUDE PREPARATION OF PPNR ON THE RATE OF NADP REDUCTION

Fraction	Addition	Rate of NADP reduction (μmoles/mg chlorophyll/h)
Chloroplasts in phosphate buffer	None	1
,, ,,	Ferredoxin	88
,, ,,	PPNR	97
50,000–144,000*g*	None	0
,,	Ferredoxin	9
,,	PPNR	110

Reaction mixtures as given for Table 2. Saturating amounts of ferredoxin or PPNR were added. Sodium ascorbate and TCIP were added to the 144,000*g* fraction only.

The 1,000*g* fraction reduced both TCIP and NADP at a faster rate than the digitonin-treated chloroplasts, the 10,000*g* fraction was less active than the 1,000*g* fraction and the other fractions were either inactive or had very low activity. Sodium ascorbate and TCIP had an inhibitory effect on the rate of NADP reduction by untreated chloroplasts or by the 1,000*g* and 10,000*g* fractions, but it stimulated greatly the rate of reduction by the 50,000*g* and 144,000*g* fraction and the 144,000*g* supernatant. In fact, the rates of reduction of NADP by the 144,000*g* fraction and the 144,000*g* supernatant in the presence of ascorbate and TCIP were of the same order as the reduction rate by intact chloroplasts with NADP alone.

Impure photosynthetic pyridine nucleotide reductase (PPNR) as obtained by an acetone fractionation of a spinach leaf extract[8] may be separated by chromatography on DEAE cellulose into a flavoprotein enzyme, and a non-hæm, iron-containing protein, named ferredoxin[9]. Plastocyanin[10], a copper-containing protein, also may be separated from ferredoxin on columns of DEAE-cellulose. In the present work, it was found that NADP reduction by the 144,000*g* fraction was restored by adding crude PPNR, but not by ferredoxin, whereas with chloroplasts, crude PPNR or ferredoxin restored activity (Table 3). It is assumed, therefore, that the flavoprotein or plastocyanin[11] or both had been lost from the small particles.

After incubating chloroplasts for 30 min in 0·5 per cent digitonin, about 25 per cent of the total chlorophyll of the chloroplast was associated with chlorophyll-containing particles which were capable of photoreducing NADP at a high rate if they were supplied with an electron donor. This approximate estimate was obtained by summing the chlorophyll contents of the 144,000*g* fraction and the high-speed supernatant and adding one-third of the chlorophyll content of the 50,000*g* fraction. (The 50,000*g* fraction is only one-third as active as the 144,000*g* fraction.) Increasing the incubation time in digitonin to 21 h resulted in a small increase only (to 30 per cent of the total chlorophyll) in the amount of chlorophyll associated with particles which were able to reduce NADP at a high rate. After 72 h in 0·5 per cent digitonin, the amount was 37 per cent, but after 72 h in 2 per cent digitonin, the figure was 49 per cent.

Irrespective of the time of incubation or concentration of digitonin, the chlorophyll *a*/chlorophyll *b* ratios of the 144,000*g* fraction and the high-speed supernatant remained about the same, whereas the ratios of the 1,000*g* and 10,000*g* fractions decreased slightly with time of incubation. Thus, in an experiment where the incubation time in 2 per cent digitonin was 72 h, the chlorophyll *a*/chlorophyll *b* ratios of the 1,000*g* and 10,000*g* fractions were 2·18 and 2·08, respectively.

These experiments provide evidence for the suggestion that the chlorophyll of the spinach chloroplast is associated with two different particles. One type of particle with a chlorophyll *a*/chlorophyll *b* ratio of approximately 6 is rendered soluble by digitonin. The other particle apparently is attached much more strongly to the structural proteins of the chloroplast grana, since it is not 'solubilized' by the digitonin treatment. It has a chlorophyll *a*/chlorophyll *b* ratio of approximately 2, compared with 3·0 for intact chloroplasts. The total chlorophyll of the chloroplast appears to be divided about equally between the two particles.

Since the chlorophyll-containing particles which are rendered soluble by digitonin have a high proportion of chlorophyll *a*/chlorophyll *b* compared with intact chloroplasts and are able to photoreduce NADP only if provided with an electron donor, it is tempting to speculate that these particles belong to system 1, whereas the chlorophyll which is not rendered soluble by treatment with digitonin for long periods is an integral part of system 2. If this hypothesis is correct, then chlorophyll *a* and chlorophyll *b* are associated with both pigment systems.

Arnon *et al.*[12] have suggested that the pigment of system 2 is chlorophyll *b*, since an action spectrum for oxygen evolution by chloroplast fragments, using an indophenol dye as oxidant and in the presence of ferricyanide, showed a peak of 644 mμ. Müller, Fork and Witt[13] isolated system 2 from system 1 in a similar way to Arnon *et al.*, but instead of oxygen evolution they measured absorption changes at 515 mμ, which are thought to be due to the reaction of plastoquinone with the pigments of system 2. Their action spectrum showed a peak at 674 mμ and a shoulder at 650 mμ, implicating both chlorophyll *a* and chlorophyll *b* in system 2.

Further work is in progress to determine the structure, composition and function of the chlorophyll-containing particles.

INCIDENCE OF THETA RHYTHM PRIOR TO AWARENESS OF A VISUAL STIMULUS

By DR. N. F. DIXON
Department of Psychology, University College, London
AND
DR. T. E. LEAR
Department of Psychological Medicine, University College Hospital, Gower Street, W.C.1

IN the course of an investigation of the EEG correlates of awareness for, and recognition of, verbal stimuli (Dixon and Lear)[1], we carried out an independent analysis of changes in the theta component of the EEG.

In this investigation the EEG was recorded from the occipital area during the gradual increase in intensity of visually presented words. Four emotional and four neutral control words of equal length and frequency, selected

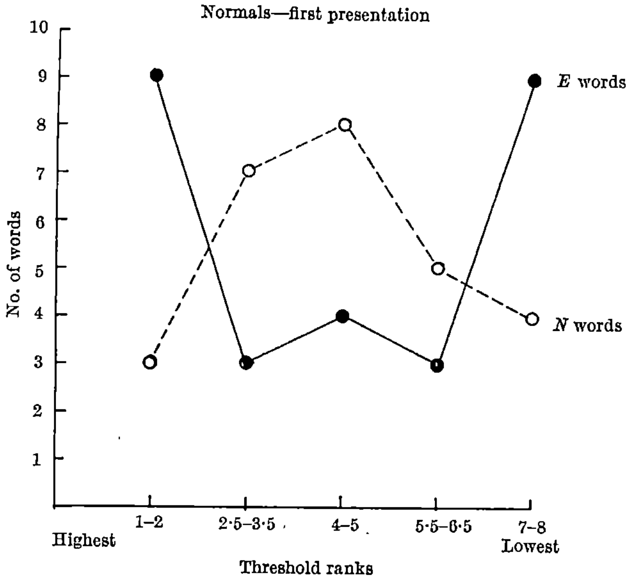

Fig. 1. Distribution of threshold ranks for emotional (*E*) and neutral (*N*) words

on the basis of results from a word association test, were presented twice each in a random order to each of fifteen subjects. Of these subjects eight were psychiatric patients of University College Hospital, and seven normal adults of approximately the same age and intelligence quotient levels as the patients. Of the patients four presented with predominantly paranoid features while four were predominantly depressed.

EEG and threshold data were recorded on magnetic tape prior to frequency analysis by a Muirhead low-frequency analyser. The EEG was quantified over 6-sec epochs by passing the output from the analyser through a low-inertia motor-driven counter.

Three general hypotheses were investigated: (1) Thresholds for emotional words would be higher or lower than those for neutral words. (2) Differences in theta abundance between emotional and neutral word presentations recorded prior to awareness of these words would exceed those recorded for a control group to whom words were not in fact presented. (3) Changes in theta abundance between stimulus onset and awareness would be greater during those presentations in which high or low thresholds were recorded than in those for words in the middle of the threshold range.

Stimulus emotionality and awareness threshold. The eight words shown to each subject were ranked in order of the intensity at which they first became perceptible.

The following curve shows the distribution of rankings for emotional and neutral words in respect of normal subjects on the first presentation. Similar curves were obtained for patients and for normals on the second presentation. The main finding that thresholds tended to be high or low for emotional words and clustered round the centre of the threshold range for neutral words is significant on the first presentation, for normals and patients combined, at the 0·6 per cent level of confidence (sign test). On the second presentation results for normals are significant at the 0·8 per cent level of confidence and for normals and patients together at the 5 per cent level. They may be taken to imply some discrimination of meaning prior to awareness of the stimulus items.

Experimental versus control group. To control against the possibility that observed differences in EEG, as between presentation of emotional and neutral words, might be artefactual, recordings from the experimental group were compared with those from a group of six normal controls. These subjects were given a treatment identical with the others except in so far as no words were presented. As with the experimental EEG's, each control record was broken down into 6-sec epochs and each trial designated 'emotional' or 'neutral' according to the paradigm ENNE NEEN. Each trial was approximately 1 min in length, equivalent in the case of the experimental subjects to the period between stimulus presentation and verbal recognition. The following mean differences in integrator scores between 'emotive' and 'neutral' word trials were obtained for the two groups of subjects over all eight trials.

Theta abundance and the awareness threshold. The following curves, for patients on the first presentation,

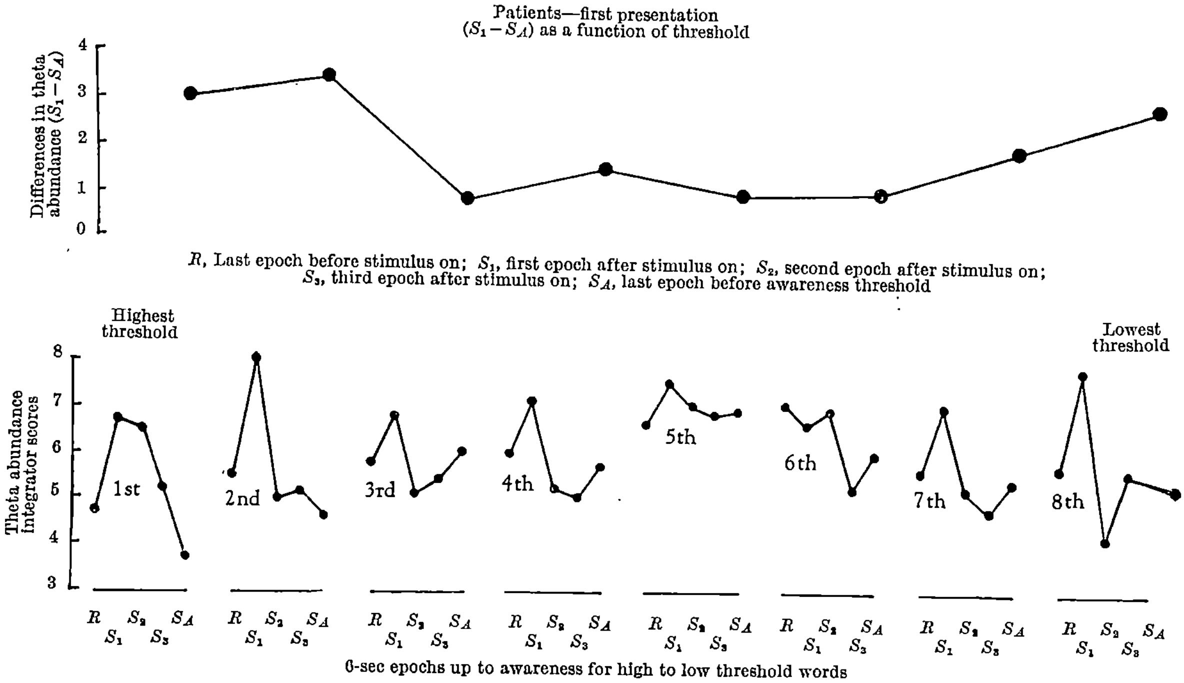

Fig. 2. Theta abundance as a function of threshold

show the incidence of theta, in 6-sec epochs between onset of the stimulus and awareness, as a function of the awareness threshold. Comparable curves showing the same generally 'U'-shaped relationship between theta activity and threshold were obtained for the patients' second presentation and for normals on the first presentation.

(Since the length of time between stimulus onset and awareness varies from subject to subject the convention was adopted of labelling the first 6-sec epoch after stimulus onset as S_1 and the last epoch before awareness as S_A; S_2 and S_3 represent means over two 6-sec periods of the intervening epochs.)

From these results the following observations may be made:

(1) For the first 6 sec after presentation of the stimulus there was a general tendency for theta to rise. For the patients in the first presentation this rise in theta, shown by all but one subject, was significant at the 2 per cent level of confidence by a two-tail test ($t = 3{\cdot}22$).

The normals as a group showed the same general effect but to an insignificant extent. However, a breakdown of the normal group into those with higher and those with lower thresholds for emotional as opposed to neutral words revealed an interesting fact. Whereas the high-threshold group showed a large rise in theta, the low-threshold group showed an almost equally large fall. The difference between these groups was significant at the 2 per cent level of confidence by a two-tail test ($t = 3{\cdot}64$). A breakdown of the patient group into high- and low-threshold subjects revealed the same tendency at work though not to a statistically significant extent.

As with the patients, the normals showed a greater rise for the four words for which they had the highest threshold. For normals that word for which they had the highest threshold evoked a rise in theta which was significant by a two-tail test at the 2 per cent level of confidence ($t = 3{\cdot}49$). For normals and patients combined this result was again significant at the 2 per cent level of confidence by a two-tail test ($t = 2{\cdot}86$).

(For both patients and normals this rise in theta during the first 6 sec of the stimulus contrasts with a fall in abundance of the alpha component. In the case of the patients this difference between alpha and theta change is just not significant at the 5 per cent level by a two-tail test ($t = 2{\cdot}3$). Like the patients the normals also showed a fall in alpha which was greater for the low-threshold words than for the high-threshold words.)

(2) Between the first epoch after the stimulus was presented and the awareness threshold there was a fall in theta (S_1–S_A), which was greater for the two words with the highest threshold and the two with the lowest threshold than for those four words in the middle of the threshold range.

Over all subjects on the first presentation this finding is significant at the 5 per cent level of confidence by a one-tail test ($t = 1{\cdot}78$). Nine out of the fifteen subjects showed this effect.

Table 1. DIFFERENCES IN THETA ABUNDANCE BETWEEN EMOTIONAL AND NEUTRAL WORD PRESENTATION

First presentation		Second presentation	
Experimental subjects	Control subjects	Experimental subjects	Control subjects
23·5	5·7	10·3	5
6·3	0·7	10·0	6
7·5	4·1	13·0	0
22·5	7·1	11·7	6·3
45·0	0·4	8·1	0·9
6·9	0·7	11·4	0·3
9·3		19·0	

By the Mann–Whitney 'U' Test these scores differ significantly from each other at high levels of confidence ($P_1 < 0{\cdot}002$, $P_2 < 0{\cdot}001$).

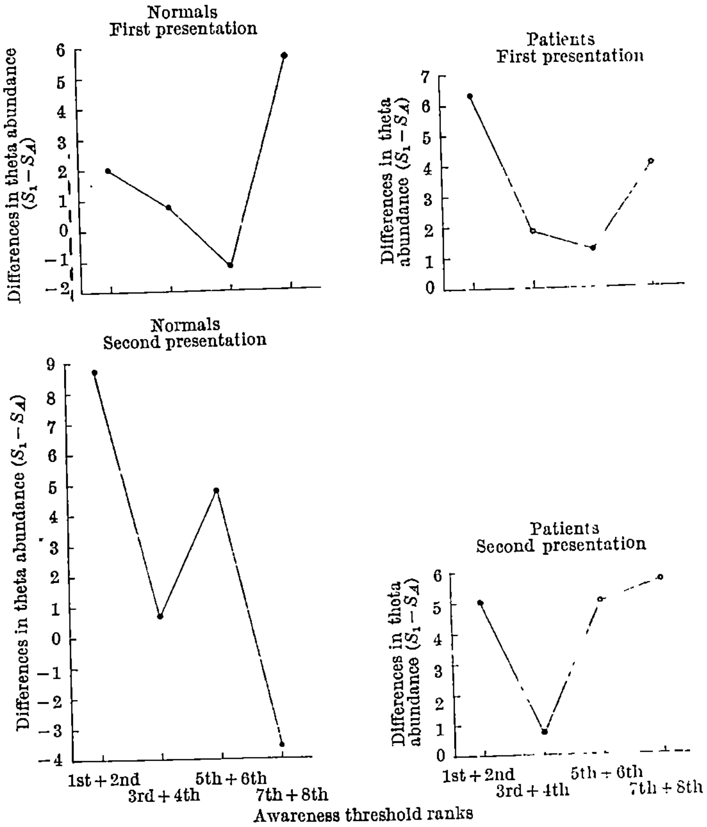

Fig. 3. Differences in theta abundance between first epoch after stimulus presented and last epoch prior to awareness as a function of the awareness threshold

(3) On the second presentation, six of the eight patients showed the same tendency. This result did not reach statistical significance.

The normals, however, on this presentation did not, as they had previously done, show a 'U'-shaped relationship between theta and threshold. Whereas they showed a fall in theta for high-threshold words they showed a progressive rise for the two low-threshold words. Within this group the difference in theta change between high- and low-threshold words was significant at the 5 per cent level of confidence by a two-tail test ($t = 2{\cdot}7$).

The difference between patients and normals in this respect on the second presentation was also significant at the 5 per cent level of confidence by a two-tail test ($t = 2{\cdot}27$).

(4) As with the analysis of the alpha component reported in a previous paper, subjects in each group were divided into sub-groups depending on whether or not their average threshold was higher for *E* words as opposed to *N* words. Applying this breakdown to the relationship between theta change from stimulus onset to awareness (S_1–S_A), and thresholds for the individual words, it is apparent that the a/m 'U'-shaped relationship holds most markedly for those normals and patients who had lower thresholds for '*E*' words than for '*N*' words. For those subjects with higher thresholds for '*E*' words, however, there is the suggestion of a difference between patients and normals. Whereas the former again showed a 'U'-shaped relationship between theta fall and threshold the normal group showed a relationship between theta and threshold that was negatively correlated (rho = − 0·79) with that recorded for the normal low-threshold group.

It is interesting to note that this difference between the normal subjects with higher thresholds for '*E*' words, and all other subjects, was very much more marked in the case of the alpha component. In the case of the high-threshold normals only, there was a significant tendency for alpha to fall more during the presentation of medium-threshold words than for those words for which these subjects had either a high or a low threshold ($t=5\cdot17$ $P<0\cdot05$ 2-tail). In this respect these subjects differed significantly from both the high- and low-threshold patient groups at 1 and 5 per cent levels of confidence respectively ($t=5\cdot6$ and $3\cdot11$) by two-tail tests.

First and second presentations. (1) Whereas the patients showed the same 'U'-shaped relationship between theta fall (S_1–S_A) and awareness threshold on both presentations, the normals only showed this tendency on the first presentation.

(2) For both normals and patients there was a significant relationship between thresholds on the first presentation and theta abundance on the second presentation.

It is apparent from Table 2 that those subjects with a higher mean threshold for emotional than for neutral words on the first presentation showed a greater theta abundance for emotional words than for neutral words, in the last epoch prior to awareness, on the second presentation.

Table 2

First presentation Awareness threshold	Second presentation Abundance prior to awareness	
	$\theta E>\theta N$	$\theta E<\theta N$
$AE>AN$	6	1
$AE<AN$	0	8

Similarly, those with a lower threshold for emotional words on the first presentation showed less theta for these same words than for neutral words on the second presentation.

By the Fisher-Yates test this finding is significant at the 1 per cent level of confidence by a two-tail test (computed P for a two-tail test $=0\cdot0028$).

The recognition threshold. Above the awareness threshold stimulus intensity continued to rise until the subject reported recognition of the stimulus word. An analysis was made of:

(1) The relationship between the recognition threshold and the emotionality of the stimulus. For the normals a 'U'-shaped relationship similar to that for the awareness threshold still held. On both presentations emotional words tended to be recognized earlier or later than neutral words. For the patients, however, the emotional words appeared to result in high thresholds only. Over both normals and patients the tendency for the highest emotive word threshold to exceed the highest neutral word threshold and the lowest emotive word threshold to be lower than the lowest neutral word threshold was significant at the 2·5 per cent level of confidence.

(2) The relationship between the recognition threshold and theta abundance in the epoch immediately prior to the recognition threshold. Here, there was a general tendency for theta to be less for an emotional word than for a neutral word, irrespective of the actual threshold value. In this respect theta behaved differently from alpha. For alpha it was found that whereas those subjects with higher thresholds for emotional than for neutral words showed more alpha for emotional than for neutral words, subjects with lower thresholds for emotional words showed the opposite effect. This finding is significant at the 5 per cent level of confidence by a one-tail test. It supports our main hypothesis that threshold regulation depends on control of cortical activation.

Conclusions. The findings described in our previous article provided some support for the hypothesis that high or low thresholds for visually presented words depend, respectively, on decreased or increased activation of the occipital cortex. This conclusion was based on the fact that subjects with raised thresholds for 'emotional' words showed less desynchrony in the pre-awareness EEG than did those with lowered thresholds for emotive material. Implicit in this finding was the fact that at some level of stimulus intensity below the awareness threshold a differential response to the meaning of the material must have occurred. It was tentatively suggested that short-term changes in alpha abundance observed immediately after onset of the stimulus reflected this initial discrimination.

Our present analysis of changes in slow-wave abundance suggests that stimulus emotionality and slow-wave activity bear a 'U'-shaped relationship to both the awareness and recognition thresholds. In the light of the relationship between slow waves and emotional arousal reported by other workers it is thought that the rise and fall of theta abundance prior to awareness of high- and low-threshold words reflect the emotional arousal occasioned by these words. The problem remains as to why this arousal should sometimes initiate cortical activation with consequent lowering of the visual threshold and at other times a lack of activation with a heightened awareness threshold.

One possible explanation is that these results reflect successive stages in what is really a single process.

The reception of an emotionally arousing stimulus initiates an immediate burst of slow-wave activity accompanied by suppression of alpha. With this suppression there occurs a momentary lowering of the cortical discrimination threshold and possibly awareness of the stimulus.

If the awareness threshold is not reached, however, because of insufficient emotional arousal, a second stage of reception occurs wherein the temporarily heightened cortical discrimination brings about a progressive inhibition of the recticular activating response. The direct consequence of this would be a raising of the visual threshold. In terms of the EEG this raising of the awareness threshold would be accompanied by a return of synchronous alpha activity and, along with the lowering of emotional arousal, a disappearance of slow waves.

(These hypotheses are consistent with the curvilinear relationship between threshold and anxiety found by Bruner and Postman[3], De Lucia and Stagner[4], and McClelland and Liberman[5].

They are also consistent with relationships between the EEG and emotion that have been described by Hoagland[6], Jost[7], Sherman and Jost[8], and Grinker and Serota[9], while data on EEG changes in pre-conscious stages of the perceptual process have been provided by Ricci and Collatina[10].

Finally, some evidence for the fact that a momentary lowering of the visual threshold precedes its raising by a visual stimulus comes from a previous experiment[11], in which it was found that during the 30-sec subliminal presentation of an emotive stimulus to one eye the threshold of the other eye fell before rising to a level above that occasioned by the presentation of neutral stimuli.)

However, these are mere conjectures which anyway fail to account for several of our *post hoc* results such as the differences between patients and normals, and between first and second presentations of the stimulus.

This work was supported by a grant from the Mental Health Research Fund.

LETTERS TO THE EDITOR

RADIO ASTRONOMY

Detection of Fine Structure in the Crab Nebula at 38 Mc/s

SEVERAL observations of the distribution of radio brightness across the Crab Nebula have been reported over a wide range of frequencies[1,2,4-6]. The results indicate that the distribution, while slightly elongated, has an approximately Gaussian profile. There is some evidence that the angular diameter increases at the lowest frequencies[1], but no fine structure has been detected. Kuz'min and Salamonovich[6], observing at a wave-length of 8 mm, noted a small source slightly displaced from the centre of the nebula which they ascribed to an independent source of thermal origin.

During the course of an investigation of the scattering of radio waves in the solar corona and the interplanetary medium[3], new information has become available on the angular diameter of the Crab Nebula at a frequency of 38 Mc/s. These results show that fine structure is present which has not been detected at higher frequencies but give no evidence of a significantly increased angular diameter. Further results derived from a recent lunar occultation of the nebula support these conclusions (see following communication).

The observations at 38 Mc/s were made with phase-switching interferometers on an east–west baseline. The arrangement of the aerials for spacings of 200 and 560 wave-lengths has been described elsewhere[3]. For spacings of 903 and 1,290 wave-lengths a system of higher sensitivity was devised which incorporated grating arrays to produce a reception pattern having a triple response. One array was a corner reflector 3,000 ft. in length containing dipole elements spaced by 1·4 wave-lengths and the other was a similar array 800 ft. in length. Signals from the distant array were conveyed to the receiver by a direct cable link. The Crab Nebula was observed at meridian transit, corresponding to an east–west aerial separation of 1,290 wave-lengths, and also at times displaced by ± 3h 20m from the meridian transit, which gave projected spacings of 903 wave-lengths.

The different systems were calibrated with reference to the source 3*C* 123, which is known to have an angular diameter $< 12''$. At the larger aerial spacings 3*C* 123 and the Crab Nebula yield comparable fringe amplitudes so that calibration is simple and direct. No attempt was made to determine the absolute phase of the fringes.

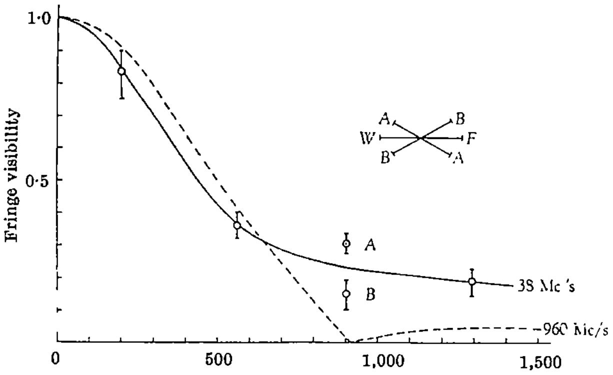

Fig. 1. The fringe visibility curve derived from observations of the Crab Nebula at 38 Mc/s. The broken line indicates corresponding results at 960 Mc/s

The fringe visibility curve derived from our measurements is shown in Fig. 1. The two points at a spacing of 903 wave-lengths correspond to different position angles of the fringes as indicated. By comparison with the results of Maltby and Moffet[4], also shown in the figure, it is clear that observations at 38 Mc/s indicate fine structure which is not present at higher frequencies. The simplest model which may be chosen to fit the observed visibility curve comprises two Gaussian sources having east–west angular diameters of $3'\cdot 7 \pm 0'\cdot 5$ and $30'' \pm 15''$. The flux densities of the two components are in the ratio of approximately 4 : 1. This result has been confirmed by recent observations of a lunar occultation of the nebula at 26 Mc/s which suggest that the small diameter component becomes even more pronounced at lower frequencies (following communication).

Radio Observations of the Crab Nebula during a Lunar Occultation

ON April 16, 1964, a lunar occultation of the Crab Nebula was observed at Cambridge at 408, 178, 81·5 and 26·5 Mc/s. East–west interferometers were used at all frequencies and strip brightness distributions were obtained across the nebula in two directions.

The path of the radio source relative to the Moon is shown in Fig. 1. Immersion and emersion of the optical centre of the nebula occurred at position angles, measured on the Moon from north positive to east, of 43° and 295° respectively. The directions *OB* and *OA* (Fig. 1) correspond approximately to the major and minor axes of the optical object, the size of which is about 6′ arc by 4′ arc in these two directions. The Moon crossed the source at the rate of 22″ arc per minute of time perpendicular to the limb during immersion and emersion.

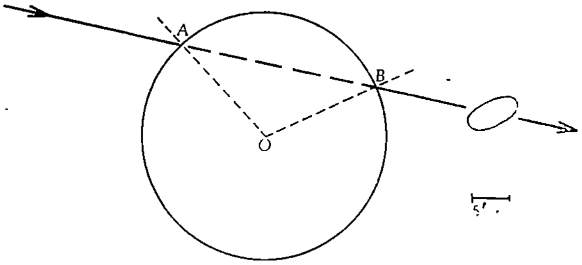

Fig. 1. Path of the Crab Nebula relative to the Moon

At 408 Mc/s the source was tracked continuously using two 60-ft. diameter paraboloids at a separation of 225λ. The 178-Mc/s observations were made with two 8λ corner reflector aerials separated by 130λ. It was necessary to move these aerials in azimuth between immersion and

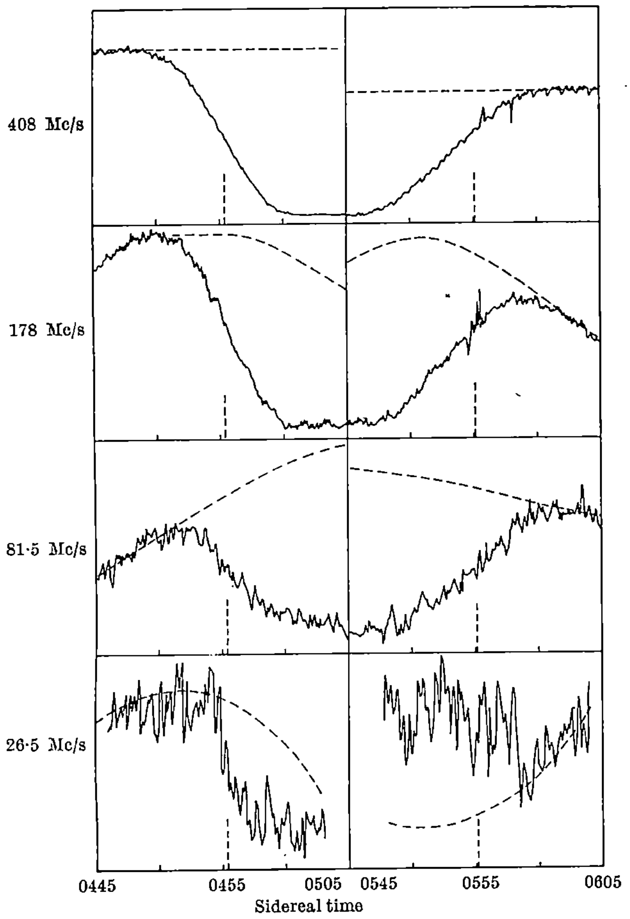

Fig. 2. Records obtained at immersion and emersion

emersion. At 81·5 Mc/s, two $2\lambda \times 2\lambda$ broadside arrays 130λ apart were used to observe both events, and the 26·5-Mc/s aerial consisted of two arrays of 30 full wave dipoles at a separation of 5λ.

At the three higher frequencies information was recorded on punched tape for computer processing, while the 26·5-Mc/s records were analysed by hand. Receiver time constants of 2 sec were used at all frequencies and the systems were calibrated by trial runs on at least one other day.

The immersion and emersion records are shown in Fig. 2; the 26·5-Mc/s records have been smoothed with an effective time constant of 12 sec. The predicted times of disappearance and reappearance of the optical centre of the Crab Nebula are shown by vertical dotted lines; comparison records for the unocculted source are also shown, indicating the variation of receptivity with those systems using fixed aerials.

The occultation curves were analysed to obtain strip brightness distributions along the two directions OX and OY (Fig. 3). The curves in Fig. 4 show the variation along XOX' and YOY' of the relative intensity of the slightly curved strips perpendicular to these directions. The analysis was based on strips 11″ arc in width. The curves are normalized so that each encloses the same area.

At immersion the strip brightness distributions at 408 Mc/s and 178 Mc/s are similar, but the 81·5 Mc/s distribution shows a greater central condensation (Fig. 4*a*). The 26·5 Mc/s curve is significantly different with a much more localized source, as is evident from the faster disappearance of the source (Fig. 2). At emersion, the three higher frequency strip distributions are noticeably flattened across the central region (Fig. 4*b*). This fact, when combined with the immersion distributions, suggests emission from a cylindrical or ellipsoidal shell. At 26·5 Mc/s much of the radiation is again seen to originate in a small region of the nebula.

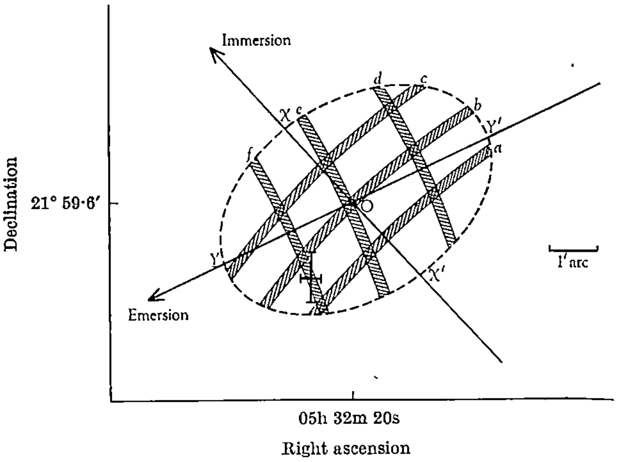

Fig. 3. Outline of Crab Nebula showing directions of travel of the Moon's limb. The position is given in 1964·3 co-ordinates

It is seen from Fig. 4*b* that there is a systematic movement of the radio centre along the major axis towards the east with decreasing frequency; this movement is too great to be attributed to refraction in the lunar atmosphere[1,2]. The position of the localized region at 26·5 Mc/s is 1·2′ arc east of the optical centre along strip *b* (Fig. 3). This position is near a prominent filament in the nebula.

The localized strip of intense emission observed at 26·5 Mc/s on both immersion and emersion indicates the presence of an area having an angular diameter of about 20″ arc which contributes 30–50 per cent of the total emission from the nebula at this frequency; its brightness temperature must exceed 10^9 °K.

In order to examine the spectrum of the emission from different parts of the source, the contributions from each

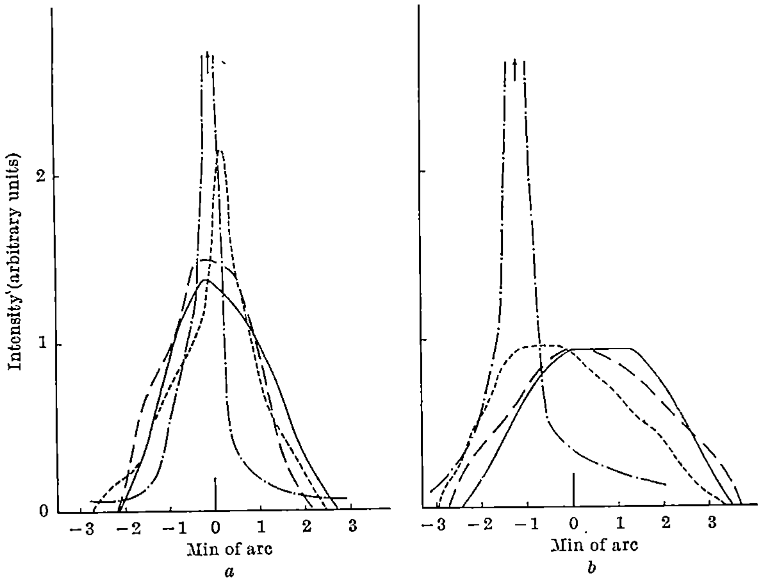

Fig. 4. Strip brightness distributions across the Crab Nebula. (*a*) Immersion; (*b*) emersion. ——, 408 Mc/s; – –, 178 Mc/s; - - -, 81·5 Mc/s; —·—, 26·5 Mc/s

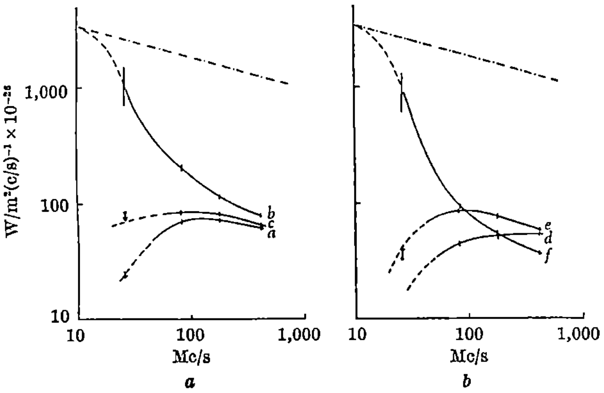

Fig. 5. Spectra of the strips *a* to *f* shown in Fig. 3. (*a*) Immersion; (*b*) emersion

of the six strips shown in Fig. 3 have been determined at each frequency and plotted in Fig. 5; the spectrum of the emission from the whole source can be approximated very well by a straight line having a gradient of – 0·27 (refs. 3 and 4), and this is shown by the dotted line. It can be seen that except for the strips (*b*) and (*f*), which contain the localized low-frequency source, there is little variation in the spectrum from different parts of the nebula; the well-defined reduction in the emission at frequencies below 50 Mc/s suggests that there may be a cut-off in the electron energy spectrum.

A further investigation of the nebula was made at 408 Mc/s using an interferometer with spacings up to $1{,}450\lambda$; these observations showed the presence of a localized source having an intensity of about 2 per cent of the total.

The position of the source is shown in Fig. 3, and agrees within the limits of error with the position obtained at 26·5 Mc/s.

The spectrum of the localized source is shown in Fig. 6. The 26·5-Mc/s points were obtained from the strip brightness distributions (Fig. 4) at immersion and emersion. At 81·5 Mc/s the intensity of the central condensation at immersion is shown together with the limit detectable at emersion for a source of similar diameter. At 178 Mc/s and 408 Mc/s upper limits for the emission from the localized source are shown. Also included are the 38-Mc/s point obtained by Hewish and Okoye (preceding communication) and the 408-Mc/s value of 2 per cent discussed above. It is seen that the spectrum of the small region is straight with the very steep gradient of – 1·2.

The physical nature of this small source is unknown. Woltjer[5] has shown that models for emission from the Crab Nebula cannot be constructed in terms of electron energy spectra uniform throughout the source. It seems significant that a source containing two regions with such unusual spectra should have a resultant spectrum which is so remarkably straight. A possible interpretation could be that electrons with a differential energy spectrum of the form:

$$N(E)\,dE \propto E^{-\gamma}\,dE$$

are produced, but the low-energy electrons are trapped in the localized region while the high-energy electrons escape into the rest of the nebula.

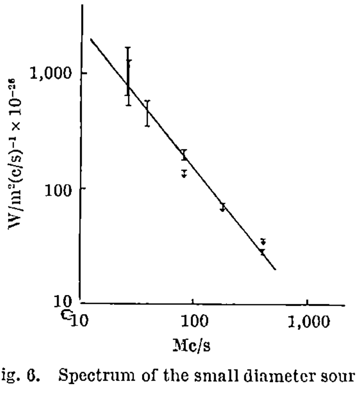

Fig. 6. Spectrum of the small diameter source

The general form of the observed radio spectra for the main body of the nebula resembles that produced by an electron energy spectrum with a low-energy cut-off. Using the formulæ given by van der Laan[6], and assuming a magnetic field of 10^{-3} gauss[7], the spectra of the nebula suggest a value of $\gamma \sim 1\cdot6$ and a low-energy cut-off at ~ 100 MeV.

We thank Prof. M. Ryle and Dr. P. F. Scott for their assistance with the observations, Miss J. A. Bailey for undertaking the numerical analysis, and Mr. W. Nicholson of H.M. Nautical Almanac Office for providing details of the circumstances of the occultation.

RADIOPHYSICS

Spectrum of the Galactic Radio Emission between 1·5 and 10 Mc/s as observed from a Satellite

THE *Alouette* satellite (1962 β α 1) carries an ionospheric sounder in a nearly-circular orbit at a height of about 1,000 km. This experiment provides data on the electron number density at and below the satellite, and on the local magnetic field strength[1]. In addition, since the automatic-gain control voltage of the sweep-frequency receiver is telemetered to the ground, simultaneous measurements are also made of the background radio noise. (The receiver is inactive during the pulse transmission, and the included integration circuit essentially removes any effects of the echo pulses from the recordings of the automatic-gain control voltage.) Accordingly, for frequencies below those which can penetrate the ionosphere, these background noise data contain information on extra-terrestrial radio sources; the accompanying ionosonde data help to describe the propagation and reception of such cosmic radio waves by the satellite. In this communication the results of the galactic noise measurements as a function of frequency are outlined; they will be discussed in more detail elsewhere, as will the observations of other extra-terrestrial sources.

Essential features of the receiving system are the two orthogonal dipoles on the satellite, of length 150 ft. and 75 ft. Impedance matching networks broaden and shape their frequency response, and the two outputs are applied, in parallel, to the receiver. In the range 1·5–12 Mc/s the transmission losses in the antenna system vary between about 1 and 9 decibels (for the antennæ in free space), but below 1·5 Mc/s the system response drops very rapidly. In the presence of an ionized plasma this antenna system response is altered somewhat; nevertheless, 1·5 Mc/s is still a practical lower limit for observations of the background noise. A practical upper limit for such observations is set by the F-layer critical frequency at the particular time and location.

The receiver gain was calibrated before launch, but absolute power calibration could not be provided in flight. Equipment voltages in the satellite are stabilized, as is the vehicle temperature to a considerable extent, so that changes in the gain of the receiver are expected to be minor. In fact, the data for the 19-month period since launching are consistent enough to suggest that no significant gain changes have yet occurred. Moreover, the computed absolute brightness temperatures for frequencies greater than 4 Mc/s are in fairly good agreement with ground-based measurements when allowances are made for differences in antenna apertures.

In-flight frequency calibration of the records is carried out automatically, and for each recording (one sweep through the frequency range takes approximately 12 sec) an ionogram is available to describe the surrounding plasma. The plane of the satellite orbit processes about ·1 degree per day in space, and records are now available that cover all regions of the celestial sphere. Records are also available for a variety of ionospheric conditions and the antenna performance can be assessed quantitatively by comparing data obtained under these differing conditions.

In scaling records, data are not used below 1·5 Mc/s because of poor sensitivity, nor are they used for frequencies that lie too close to the ionospheric resonances[2]. This means that those spectral regions are avoided in which the propagation conditions and antenna performance are most difficult to assess: this procedure also limits the effective aperture to half-cone angles greater than 50°. In general, records have been selected so as to omit the regions toward the centre of the Galaxy, although with the broad effective antenna aperture used this distinction is not always meaningful at the higher frequencies. The relative received power as a function of frequency was scaled from the recordings for a wide range of local electron number densities and for different local magnetic field strengths. No apparent dependence on the orientation of the satellite antennæ was found in the data, nor was there any significant dependence on the local magnetic field strength except when the observing frequency approached close to the ionospheric resonances. A dependence on the local electron number density, however, was noted in the data. Accordingly, the values of the received power for a particular observing frequency were compiled and plotted as a function of the local electron density. This process was repeated for a number of other frequencies throughout the range of interest. A family of 'best fit' curves—one curve for each particular frequency—was drawn through these plotted data and extrapolated to zero electron density. Since each curve was drawn with a shape closely similar to that of its adjacent member, the errors involved in the extrapolation process are thought to be relatively small in at least half the cases. The resulting intercept values of the relative power for the particular frequencies are taken as corresponding to free space conditions; when combined with the known free space impedance for the antenna system they give values of the relative galactic brightness temperature. The relative temperature values so obtained are plotted in Fig. 1 as a function of frequency, together with error limits that allow for scatter in the observations as well as for uncertainties in the extrapolation process. This curve is to be taken as representative of medium and high galactic latitudes, and any fine detail in these regions has been smoothed out because of the large antenna aperture.

From Fig. 1 it can be seen that the most accurate results are obtained for the lower half of the frequency range. Above about 5·5 Mc/s only one accuracy limit can be given for each data point, and the indicated curve has been extrapolated from lower frequencies with a gradual increase in slope such as would bring it into agreement with the results of ground-based measurements at frequencies greater than about 15 Mc/s. It should also be noted that the indicated uncertainties do not include a provision for changes in the receiver characteristics after launch, if any occurred.

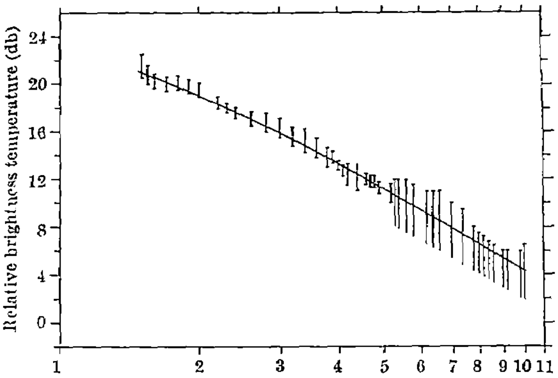

Fig. 1. Galactic noise spectrum obtained with the swept-frequency receiver in *Alouette*

A comparison of this spectrum with that obtained by Ellis, Waterworth, and Bessell[3] from ground-based equipment shows a significant difference, as may be seen in Fig. 2. Here the solid curve represents the results of Ellis *et al.* for high galactic latitudes, and the dashed curve has been obtained from Fig. 1 by converting relative brightness temperatures to relative flux densities. The two curves have been normalized at 4·8 Mc/s, where the present data are thought to be quite reliable. Between 4 and 10 Mc/s there is reasonable agreement between the two curves, but this is seen not to be so for lower frequencies; the discrepancy increases with increasing wave-length. This dependence on wave-length, together with the fact that the solid curve has a terminal slope of about +2 as one would expect for radio wave absorption, suggests that absorption occurs below the satellite height—that is, below 1,000 km. In other words, it is thought that a large part of the discrepancy between the two curves of Fig. 2 can be attributed to ionospheric absorption. Since there is no description as to how Ellis *et al.* evaluated and removed the effects of ionospheric absorption from their data, it has been assumed that they underestimated the effects. Generally accepted values for the D-region electron number density are such that there should always be

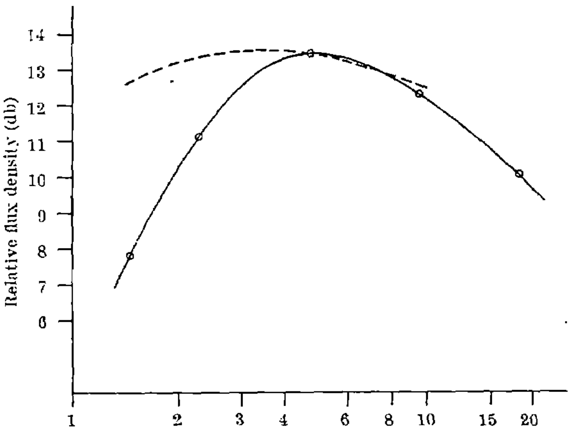

Fig. 2. The relative flux density for the galactic noise as a function of frequency; as determined from the *Alouette* data (dashed curve); and as obtained by Ellis *et al.* (solid curve)

observable absorption at these frequencies. Differences in antenna aperture in the two cases may also be important in so far as iris effects and deviative absorption are concerned in the ground-based measurements.

The importance of radio wave absorption in the Ellis *et al.* results has already been recognized by Hoyle and Ellis[4], but they attributed all the absorption to the galactic gas. This interpretation led them to a 'surprisingly high value' for the electron density in the Galaxy. If, as suggested here, the Ellis *et al.* galactic noise spectrum still includes a contribution from ionospheric absorption, the computed galactic electron densities should be reduced accordingly.

Because of the lack of in-flight equipment calibration, absolute data have been considered somewhat less reliable than relative data. Nevertheless, values for the brightness temperature have been obtained for representative regions of the celestial sphere; these suffer from the poor antenna resolution, and only the very crudest mapping is presently possible. The brightest region in the Galaxy is centred approximately on the south galactic pole and at 2·3 Mc/s has a temperature of approximately $1·8 \times 10^7$ °K. The comparable region containing the north galactic pole has a temperature at this same frequency of $1·1 \times 10^7$ °K. This differential, if it can be substantiated by further observations at such low frequencies, would seem to substantiate the asymmetrical location of the solar system with respect to the plane of the Galaxy. The lowest temperature, approximately $5·0 \times 10^6$ °K at 2·3 Mc/s, has been obtained for a region centred on R.A. 9 h, dec. + 75°.

The contributions of the many people and agencies that were involved in the various stages of the *Alouette* project and who continue to gather and reduce the data are gratefully acknowledged.

ASTRONOMY

Gravity and Rotation

It is possible to show mathematically that a particle which is located on a rotating object is attracted by all the particles of the object according to the inverse square law. Several important consequences follow as a result of this theorem. One of the most important is that Newton's second law of motion and the law of universal gravitation are not laws apart; one can be deduced from the other. Another is that gravity is due to the rotation of the Galaxy, and from this the following verifiable conclusion is obtained.

If ρ is the average density of the Galaxy, ω its angular velocity and γ the constant of universal gravitation, then

$$2\pi\gamma\rho = \omega^2$$

The present values for ρ and γ are in C.G.S. units 7×10^{-24} and $6·8 \times 10^{-8}$. Using the foregoing formula ω is $1·7 \times 10^{-15}$ radians/sec. The present value for the angular velocity of the Galaxy is given by astronomers as 10^{-15} radians per sec.

PHYSICS

Fracture of Liquids in Shear

In a recent article on melt fracture of silicone polymers under shear[1] Hutton reports that the critical shear stress for fracture in a cone and plate viscometer is independent of polymer molecular weight but dependent on cone diameter. He further suggests a criterion for predicting the onset of melt fracture. It is the purpose of this communication to discuss these points.

(1) The phenomenon of extrudate distortion in capillary flow, originally observed by Spencer and Dillon for polystyrene[2], was ascribed to 'melt fracture' by Tordella[3–5] on the basis of visual observations of polymer flow into the capillary. In their original work Spencer and Dillon found that the critical shearing stress for melt fracture, τ_d, was dependent on molecular weight, the product of τ_d and weight average molecular weight, for a series of polystyrenes, being constant. This constant was later shown to be proportional to the product of temperature, polymer density and recoverable shear strain at fracture[6]. It was found empirically that the recoverable shear strain at fracture is always about 7 ± 2 units for linear polymers, independent of polymer type. Thus the critical shear stress measurement can be used as a means for determining molecular weight[6–8]. The results entered in Table 1 of Hutton's paper[1] are thus seen to be at variance with those earlier reported results.

The results in Table 1 of ref. 1 suggest a dependence of the critical shearing stress for melt fracture on the cone geometry, a point which is elaborated in the author's theoretical approach to the melt fracture phenomenon. Here again inconsistency with earlier capillary flow data seems evident, since in this earlier work it was established[9,10] that the critical shearing stress for onset of melt fracture in extrusion investigations is independent of the geometry of the extrusion system. The geometry of the system does, however, influence the macroscopic effects of melt fracture[8,9], thus often leading to a conclusion which we believe to be erroneous that the two factors are fundamentally interdependent. Certainly the interpretation of the melt fracture phenomenon given in reference 6, and implied also by Spencer and Dillon[2], would require that τ_d be independent of system geometry.

The explanation of these discrepancies may lie in the possibility that the effects observed by Hutton are not due to melt fracture but to some other phenomenon. Certainly in capillary extrusion of polymer melts effects are noted which are not attributable to melt fracture as usually defined[11,12] but to other complex flow characteristics. This suggestion is reinforced by the fact that only two of the silicone fluids used by Hutton have molecular weights above the critical molecular weight for entanglement of this polymer[13] (~30,000). Except at very high rates of shear, non-Newtonian flow would not be expected for polymers with molecular weights lower than the critical weight for entanglement[14,15]. Further, at these low molecular weights it has been suggested that elastic effects should not be observed either[16]. The results reported by Hutton for samples *MS*200/12.500 and *MS*200/30,000 therefore raise the question whether unknown effects are not complicating the experimental evidence, and contributing to an incorrect assessment of the critical shearing stress in terms of polymer molecular structure.

(2) In addition to these purely experimental points of difference some discussion is warranted of the model postulated by Hutton, wherein the fracture will occur only when the total elastic energy is at least sufficient to supply the energy requirements of the new surface formed. This is the criterion applied by Griffith[17] to brittle fracture of glasses, where the work to form the fracture surfaces is a function of the surface tension of the material. Thus the fracture stress, σ, is related to

E, α and c, the modulus of elasticity, specific surface free energy and defect length in the sample, by:

$$\sigma \geqslant \sqrt{\frac{E\alpha}{c}} \qquad (1)$$

Application of this criterion in reference 1 leads to the prediction that surface work and shear stress for melt fracture are independent of polymer molecular weight. It is unlikely, however, that the surface tension term is at all significant in fracture of liquids, or even of metals. In most cases of fracture the work of forming new fracture surfaces is probably dependent primarily on the plastic work occurring in the brittle fracture zone ahead of a growing crack[18–22]. This plastic work must depend on a viscosity term and hence on molecular weight.

By analogy with the brittle fracture of steels one may suppose that there are three stages in the process of melt fracture[23–25].

(i) The formation of a crack of atomic dimensions is the initiation phase. The initial crack may be pre-existing, such as dirt, microgel or agglomerates of filler or pigment, or it may form initially as a result of shear stress on the flowing melt[26,27]. We are unable to distinguish between these alternatives on the basis of our present information.

(ii) The initial microcrack must grow to the critical dimension for cleavage fracture. This is the growth phase. Persistence of the crack at the dimensions required for stability could result from the piling up of minor cracks or voids at an obstacle such as a very long, entangled polymer chain. Detailed speculation must await further relevant experimentation. However, the polymer melt stream does fracture and a flaw must grow through the dimensions corresponding to the crack initiation and growth phase.

(iii) The final phase is crack propagation. The modified Griffith criterion for crack propagation in a polymer melt is that the elastic energy, E, released by the melt as the crack advances is at least equal to the work, P, to form two new crack surfaces. This work involves at least two terms: (*a*) the surface-energy work; (*b*) the plastic work. The surface-energy work will be minor compared with the plastic work. Further, the plastic work, which will depend on viscosity of the melt and the velocity of crack propagation, should depend markedly on molecular weight if only because of the viscosity dependence of molecular weight.

The elastic energy per unit volume at fracture is given by[28]:

$$E = \frac{\tau_d^2}{2\mu} \qquad (2)$$

where μ is the shear modulus of the melt. This relation is valid for a polymer which obeys Hooke's law in shear and which relaxes, after melt fracture, to zero shear stress. The problem in applying the criterion $E \geqslant P$ is to calculate P, the non-recoverable fracture work. This should be given by the product of a viscosity and a shear rate, both of which may depend on the velocity of crack propagation and crack size and geometry. It is worth noting, however, that an interesting result is obtained if the plastic work is taken as given by:

$$P = \eta_{\max}\dot{\gamma} \qquad (3)$$

where $\eta_{\max}$ is the "inelastic viscosity" and $\dot{\gamma}$ the shear rate. This $\eta_{\max}$ is defined by[6]:

$$\eta_{\max} = \frac{\tau}{\dot{\gamma}}\sqrt{1 + \frac{S_R^2}{4}} \qquad (4)$$

where S_R is the recoverable shear strain.

The condition for the Griffith criterion for melt fracture thus becomes:

$$\frac{\tau_d^2}{2\mu} \geqslant \eta_{\max}\ \dot{\gamma}_d \qquad (5)$$

It is interesting to observe in Fig. 1 that a plot of τ_d versus $\sqrt{\mu\ \eta_{\max}\ \dot{\gamma}_d}$ is linear for a wide range of both linear and branched polyethylenes, and that the slope of the curve is $\sqrt{2}$. The data are therefore consistent with the Griffith criterion, when the plastic work is given by equation (3).

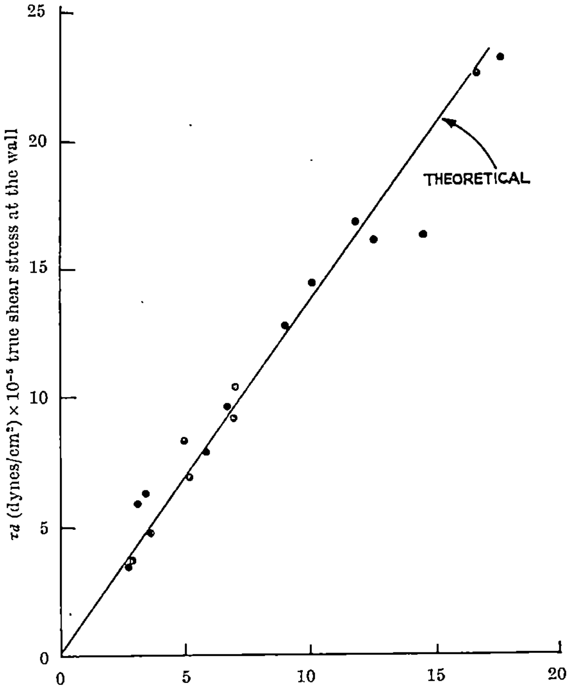

Fig. 1. The critical shearing stress for fracture, τ_d, versus $\sqrt{\mu\ \eta_{\max}\ \dot{\gamma}_d}$

The linearity of the plot in Fig. 1 is, however, to be expected. For $\frac{S_R^2}{4} \gg 1$ equation (5) can be rewritten as:

$$\frac{\tau_d^2}{2\mu} \geqslant \tau_d\,\frac{S_R}{2} \qquad (6)$$

which for equality is Hooke's law in shear. It was already known from end correction investigations of the resins in Fig. 1 that this was true, so that Fig. 1 is merely a re-statement of our results.

THE first and major point raised by Bagley, Rudin and Schreiber is that when they compare my results[1] for the onset of flow instability in cone-and-plate viscometers with those for the onset of flow instability in capillary extruders they observe discrepancies. For example, the critical shear stress in the first type of instrument is independent of molecular weight and dependent on geometry, whereas in the second type it is dependent on molecular weight and independent of geometry. They have chosen the conclusion that what I have observed and measured is some other phenomenon than the one observed in capillaries. While this may be a correct conclusion it certainly does not follow from their argument about effects of 'geometry', and I think it is an incorrect conclusion for the following reasons.

An increase in the radius of a capillary tube is, in a sense, a change of geometry, but it is not the same sort of change as that between a capillary and a cone-and-plate viscometer: and, because it has been observed that the shear stress at the onset of melt fracture is independent of tube radius, it does not follow that the stress is independent of other sorts of geometrical changes. In the theory I give for fracture I take into consideration the total elastic energy in the sheared liquid. This is the integration of elastic energy through all variations in shear field and throughout the volume of liquid. For the cone-and-plate viscometer, in which the rate of shear is everywhere constant, this integration is very simple. Since the final expression contains certain dimensions of the cone-plate system, geometrical factors are important, and I stated this clearly in the final sentence of the article. A similar calculation for a capillary tube extruder cannot possibly contain the same geometrical factors, and a facile transference of critical shear stress data from one geometry to another is therefore not permissible. On the other hand, a theory which, when applied to geometrically completely different shearing devices, gives results in agreement with experiment will probably be correct. The application of the total elastic energy concept to the case of a capillary tube does in fact lead to the prediction that the shear stress at the onset of flow instability for silicone fluids and other 'power law' liquids is independent of tube radius. This and similar calculations are to be published.

The second major point concerns the approach to fracture through the elastic energy concept. I agree that the concept is a direct descendant of Griffith's theory[2], but it is considerably modified to avoid a crack length in the final expression and to find application to liquids. Griffith's own discussion of liquid fracture is more to do with cavitation than fracture, and the method of calculating the elastic energy from the components of stress was not available to him. A puzzling feature of the analysis given by Bagley, Rudin and Schreiber is the failure to introduce a fracture criterion. There seems to be no reason why their final expression, equation (4), should not apply at any pair of values of shear stress and rate of shear and not just at the values at melt fracture. In fact the whole analysis appears to comprise a set of dimensionally consistent identities, and agreement with experiment, as they state, is to be expected.

A further point should not go unanswered. Bagley, Rudin and Schreiber, using a dubious argument about entanglements, conclude that some of the silicone fluids I studied 'would not be expected' to have non-Newtonian properties and 'should not' have elastic properties. However, these theoretical predictions are not borne out by my own measurements on silicones in the 10^2–2×10^3 poise range or by the measurements of J. J. Benbow and E. R. Howells[3] in the 10^2–3×10^5 poise range, of A. J. Barlow and J. Lamb[4] in the 8–$2 \cdot 6 \times 10^2$ poise range, of A. J. Barlow and G. Harrison[5] in the 1–10^3 poise range, and of C. C. Currie and B. F. Smith[6] in the 30–10^3 poise range.

'Hook Effect' in the Analysis of X-ray Diffraction Line Profiles

IN the analysis of X-ray diffraction line profiles by the Warren and Averbach method[1] a hook has often been observed in the particle size coefficients (A_L^P) versus distance (L) plots. In a recent work[2] on the analysis of X-ray diffraction line profiles due to cold-worked silver obtained by Geiger counter X-ray diffractometer, no such hook was observed, while in another work[3] on the analysis of X-ray diffraction line profiles of cold-worked molybdenum by a photographic method, the hook was quite pronounced. In order to investigate as to why the hook is produced in the photographic method and not in the diffractometer method, the 111 and 222 reflexions of cold-worked aluminium were examined by photographic as well as diffractometer method.

The aluminium examined was spectroscopically pure and was supplied by Johnson Matthey and Co., Ltd., London. Spectroscopic examination revealed that aluminium rod contained an estimated amount of 0·0002 per cent of silicon, 0·001 per cent of magnesium, 0·0005 per cent of iron and copper and less than 0·0005 per cent of tin, cadmium, sodium and calcium. Filings from an aluminium rod were allowed to pass through a sieve of 325 mesh/in.^{2} and the samples for the Geiger counter diffractometer were prepared in the form of flat-faced briquettes with a binder. The X-ray diffraction patterns of the cold-worked and annealed materials were measured with a Geiger counter diffractometer. To avoid the asymmetric broadening and shift of the peaks by rate meter recording the line shapes were recorded manually and fixed-count measurements were made of the diffracted intensity, at intervals in 2θ varying from 0·5° in the background to 0·01° in the lines using an electronic scaling unit and an EIT electronic counter. For a photographic method, an 11·46 cm diameter camera was used. All the films were processed under the same conditions. The line intensity measurements were carried out by an Adam Hilger non-recording type of microphotometer. The intensity scale was calibrated through suitably prepared standard wedges.

The Fourier coefficients for 111 and 222 reflexions were determined by Beevers–Lipson strips. For comparison of the Fourier coefficients of the line profiles determined by two methods, the coefficients of pure X-ray diffraction line profiles were determined by eliminating the geometrical broadening by the method of Stokes[4]. For eliminating the instrumental broadening the line profiles from fully annealed specimens were used as standard.

The high-order Fourier coefficients obtained by film as well as diffractometer method agree within 6 per cent. The agreement in the case of low-order Fourier coefficients is, however, very poor. The values of the low-order Fourier coefficients obtained by film method are less than those obtained by counter method by 12 per cent. The decrease of Fourier coefficients is perhaps due to the assumption of a high background in the film method which amounts to taking the lower area of the peaks. This decrease in area essentially affects the low-order Fourier coefficients while the effect on high-order coefficients is within the limits of experimental accuracy. The appearance of the hook in the A_L^P versus L curves in the analysis of X-ray diffraction line profiles, therefore, seems to be due to the inability of the photographic method to record properly the tailings of the X-ray diffraction line profiles.

I thank Prof. H. N. Bose, head of the Department of Physics, for the provision of laboratory facilities. I also thank Dr. G. B. Mitra for his advice, and the Director-General, Council for Scientific and Industrial Research, for the award of a senior research fellowship.

GEOPHYSICS

A Possible Interpretation of the Fast Regular Fading observed on Satellite Transmissions

Frihagen and Tröim[1] have already observed a deep and nearly sinusoidal type of fading on fast amplitude records at 108 Mc/s. The effect only lasted for a few periods and a time delay between similar features on records taken at two spaced aerials indicated that it was introduced in the ionosphere. They proposed that this phenomenon was caused by diffraction at a single 'blob' in the ionosphere and that it is similar to that which was observed in radio-star scintillation by Wild and Roberts[2]. Apparently the same kind of amplitude variations were observed on several occasions at Kiruna (67·8° N., 20·4° E.) (ref. 3) on records of *Transit IV A* at 54 Mc/s which showed intense scintillation. The phenomenon was usually more persistent than that observed by Frihagen and Tröim and often lasted up to a hundred periods. The fading periods varied between 50 and 500 msec, but there was a predominance of periods of about 100 msec. Fig. 1 gives an example of persistent regular fading lasting about 10 sec. Some cases of the phenomenon of short duration (about 1 sec) which exhibit monotonically increasing (or decreasing) amplitude and period may be explained by diffraction at single 'blob' in the ionosphere. However, it is difficult to explain long lasting, regular fading in this way.

The phenomenon was intensively investigated at Kiruna during the second half of 1962 using recording equipment described by me[3]. It was found that it occurs most frequently at rather large zenith distances, with a maximum between 40° and 50°.

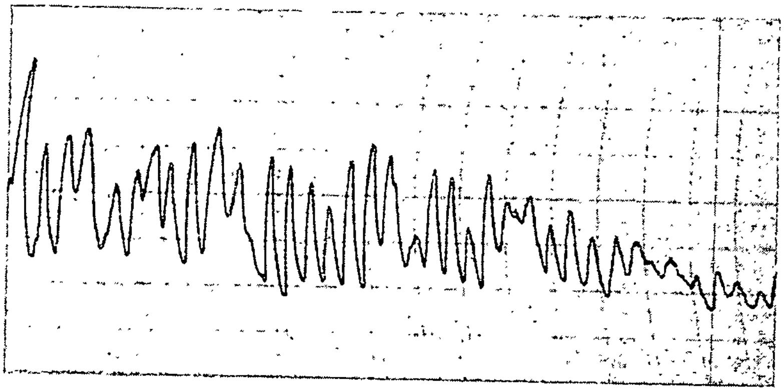

Fig. 1. An example of fast regular fading observed on rev. No. 7192. One division of the scale is 0·5 sec

The plot of sub-satellite positions at times when the regular fading was observed at Kiruna (Fig. 2) shows that in most cases the phenomenon occurred to the east or west of the observing station. Measurements made using spaced receivers usually exhibited a time delay between patterns observed at different aerials.

The following explanation of the phenomenon is proposed. The frequency of the satellite signal received at the aerial is different from the transmitted frequency, f, by an amount Δf, given by:

$$\Delta f = -\frac{f}{c}\dot{\rho} + \frac{f}{c}\frac{d}{dt}\int (1-n)dr \qquad (1)$$

where c is the velocity of light in a vacuum, and $\dot{\rho}$ is the time derivative of the geometrical length of ray path. The first term represents the Doppler effect in a vacuum and the second term is a 'correction term' which takes account of the effect of the dispersive medium between the transmitter and the receiver and where n is the refractive index of the medium and the integration is performed along the propagation path. When the transmitted frequency is high, then, using the usual notation

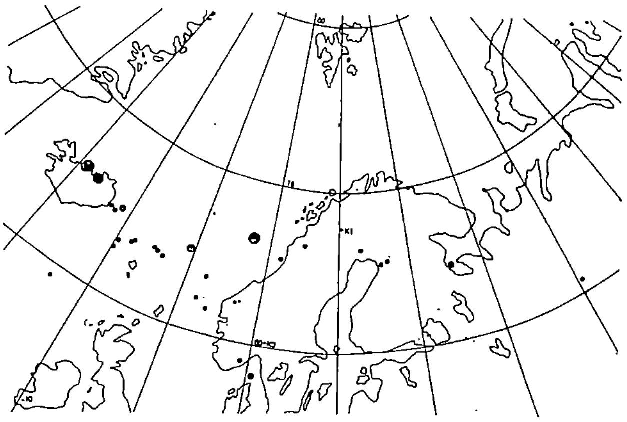

Fig. 2. Sub-satellite positions at times when the regular fading was observed at Kiruna. The diameter of circles is proportional to the duration of the fading

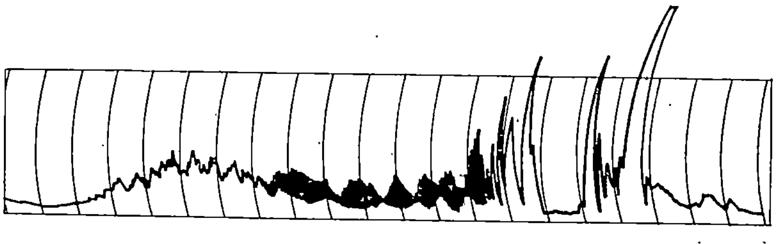

Fig. 3. An example of a record where three closely spaced frequencies are present (rev. No. 1208 of 1963–49C). One division of the scale is 5 sec

of the magnetoionic theory and rationalized M.K.S. units, the second term of equation (1) may be rewritten:

$$\frac{40{\cdot}25}{cf}\cdot\frac{\mathrm{d}}{\mathrm{d}t}\left(\int_0^{r_s} N\mathrm{d}r\right) \tag{2}$$

where the integration is performed along the propagation path up to the satellite. When the satellite signal propagates along two different paths 1 and 2, then at the aerial these two components differ in frequency by an amount:

$$F = -\frac{f}{c}\left[\dot{\rho}_1 - \dot{\rho}_2\right] + \frac{40{\cdot}25}{cf}\left[\left(\frac{\mathrm{d}n_s}{\mathrm{d}t}\right)_1 - \left(\frac{\mathrm{d}n_s}{\mathrm{d}t}\right)_2\right] = -\frac{f}{c}\,\Delta\dot{\rho} + \frac{40{\cdot}25}{cf}\cdot\Delta\left(\frac{\mathrm{d}n_s}{\mathrm{d}t}\right) \tag{3}$$

where $\Delta\dot{\rho}$ is the difference between radial velocities and $\Delta\left(\frac{\mathrm{d}n_s}{\mathrm{d}t}\right)$ is the difference between the time derivatives of the slant electron content for each propagation path. If these components have amplitudes of the same order of magnitude, the resultant signal received will be modulated by the frequency F given by equation (3). Thus, for a frequency of 54 Mc/s:

$$F = -\,0{\cdot}18\Delta\dot{\rho} + 2{\cdot}485 \times 10^{-15}.\Delta\left(\frac{\mathrm{d}n_s}{\mathrm{d}t}\right) \tag{4}$$

It is clear that both terms contribute significantly to F even if the propagation paths are only slightly different. The only condition is that both propagation paths must exist for a period large compared with $1/F$. It is obvious that larger frequencies F are more probable for large zenith distances when the influence of ionospheric refraction and slant electron content is greater. On the other hand, the amplitude of any scintillation which may obscure the regular fading also increases with zenith distance. The observed distribution of the fast regular fading is a result of these two effects.

The path difference between the two components reaching the observer, and the difference between their temporal variations when the satellite moves, may be caused in two different ways: (*a*) passage through irregularities in the total electron content; (*b*) reflexions between ionospheric layers or irregularities in the presence of sufficiently large gradients of electron density. It may also be caused by other, not purely ionospheric, effects, as abnormal tropospheric refraction or ground backscatter. There is still no experimental evidence about the magnitude of the difference in arrival angles of the two rays, so that many mechanisms are possible.

The result shown in Fig. 2 suggests that the effect occurs mainly in the auroral zone. Furthermore, radio-interferometer measurements made in Kiruna show that the effect is purely an amplitude modulation.

In one case, probably three propagation paths were present on the transmission from 1963–49*C* at 54 Mc/s. The observation was made on March 4, 1964, during a very disturbed period. The amplitude record given in Fig. 3 shows the presence of three closely spaced frequencies beating together. The fade-out of signals at the end of the period of fast fading is probably due to the interference between two waves of almost the same frequency in antiphase.

GEOLOGY

Origin of Lake Bosumtwi (Ghana)

MR. S. O. BAMPO's recent report on the "Kumasi Conference on the Lake Bosumtwi Crater"[1] raises a few questions.

In the summary of his own talk, which is part of the report, the author refers to certain deposits near Morontuo as 'brecciated conglomerates', 'conglomerates' and 'breccia'; but, in fact, only the term breccia is appropriate. Morontuo, sometimes spelled Morawtuo, is a village south-west of the Lake. The rocks concerned mainly consist of angular and subangular fragments of vesicular glass and of the surrounding Birrimian country rock with its intrusives. Junner[2] identified these deposits, which are evidently considerably younger than the underlying Precambrian rocks, as pyroclastics. This has been the main argument for the assumption by him and Rohleder[3] that the Bosumtwi depression is of (crypto-) volcanic origin. Mr. Bampo seems to consider a slight difference in composition between the glassy material from the Lake Bosumtwi breccias and dacitic pitchstone from Scotland as an argument against the volcanic theory for the first. However, variations in composition between similar volcanic rock-types from different areas are normal and form no criterion in the present discussion.

Although the passage is not very clear, it seems that Mr. Bampo suggests that only large deposits of volcanic material around a structure of the type under review provides sufficient evidence for a volcanic origin of the structure. This is not so, for any deposit of this kind, however small, indicates volcanic activity and, if clearly confined to the area of the structure, represents at least a very strong argument for a belief in such an origin. Explosive volcanic activity without lava outflow, but resulting only in the ejection of pyroclastics, is well known in geological history. In the case of Lake Bosumtwi its isolated position outside areas of contemporaneous volcanic activity is indeed a problem, but the main problem is an alternative interpretation of the 'volcanic breccias and tuffs' near the depression as products of meteorite impact ('impactites'). This suggestion has been raised after the discovery of coesite in the glassy constituents of the breccias[4]. At present much attention is being directed to this particular question.

It may be mentioned that during the post-conference excursions Prof. Gentner and Dr. Lippolt of the Max Planck Institut für Kernphysik, Heidelberg, Prof. Monod of the Institut Français d'Afrique Noire, Dakar, and I examined Junner's 'type'-localities and some of the glass containing material was collected. This material is now being investigated.

It is not clear what relevant conclusion Mr. Bampo wants to draw from his statement that there is "an elliptical distribution of alluvial carbonado type diamonds in Ghana which are associated with recent conglomerate deposits and also with deep valleys, including the Bosumtwi Crater". As emphasized by the director of the Geological Survey of Ghana, Mr. Cudjoe, during the discussion at the conference, the alluvial diamond occurrences in Ghana are known to be river concentrates from Precambrian source rocks. Diamonds have been found in the Birrimian. It is difficult to see how these occurrences could be related to the origin of the relatively young Bosumtwi structure. So far, no diamonds are known from the structure itself and its immediate vicinity.

Mr. Bampo suggests that attention be directed to the changes in level of the Lake. These changes have been considerable in the past as can be seen from the occurrence of terraced lacustrine deposits up to about 150 ft. above the present Lake level. It seems likely that climatic variations are the cause of these changes[2,5]. Further investigation into this matter is desirable, as it may contribute to the solution of the problems of the age and origin of the Lake.

Mr. Bampo mentions the numerous iron slags which occur in Ghana, including the Lake Bosumtwi area, as well as in many other places in Africa. They always seem to be associated with archæological sites in laterite-covered regions and it is beyond doubt that they are produced by human activity[6]. If it is suggested that the slags are the result of meteorite impact, then it is unlikely that they would have resisted weathering since the early Pleistocene, which is probably the age of the Bosumtwi structure.

The dense vegetation and scarcity of outcrops make it difficult to trace Rohleder's 'Drucksuturen'-locality, which is the only place where features in rocks have been interpreted as percussion marks[7]. The few outcrops of quartzite examined by us in the area during the post-conference investigations did not show anything that responded to Rohleder's description. So far as I know, no undoubted shatter cones have been found by any geologist who has searched for them in recent times, and I have never seen anything that could be interpreted as shatter cones in my visits to the site.

New Zealand Mid-Tertiary Stratigraphical Correlation

DR. D. G. JENKINS recently averred[1] that, consequent to the discovery of *Globorotalia kugleri* in rocks of Otaian age in New Zealand, our[2] correlation between the mid-Tertiary stages of New Zealand and the Cipero Formation globigerinid zones of Trinidad is 'completely wrong'.

We agree with Dr. Jenkins that *G. kugleri* is an important short-ranging species in the well-documented Trinidad Oligo-Miocene section, but his assumption that it is so in New Zealand remains to be confirmed. The period of overlap of '*Catapsydrax*' *dissimilis* and *Globoquadrina dehiscens*, also well documented, is, in the Trinidad succession[3], indicative of the *stainforthi* zone, two zones later in time than *Globorotalia kugleri*; in New Zealand '*C.*' *dissimilis* and *Globoquadrina dehiscens* are known to occur together in the Otaian[4] and underlying Waitakian (that is, U. Landon to L. Pareora). In Trinidad the overlap of these two species is within the range of *Globigerinoides 'trilobus'*[3] which, in New Zealand, ranges down to the lower Pareora; hence our approximate equation (a triple concurrent-range zonal equivalence) of the Pareora with the *stainforthi* zone.

This triple concurrence of ranges occurs, in Trinidad, after the extinction of *Globorotalia kugleri*, so Dr. Jenkins's record of this species "from Otaian samples from North Auckland" raises problems surprisingly ignored in his communication. If it is assumed that the planktonic zonal sequence is the same and that the ranges of the species are effectively isochronous in Trinidad and New Zealand, then either: (*a*) the samples from North Auckland containing *G. kugleri* are older than the *stainforthi* and *dissimilis* zones and hence pre-Pareora in age, or (*b*) the samples are Otaian and another species has been misidentified as *G. kugleri*. On the other hand, if it is accepted that the planktonic zonal sequence is similar, but that ranges of all species are not essentially identical in Trinidad and New Zealand, then either (*a*) *G. kugleri* ranges up to the *stainforthi* zone (as delimited by the *dissimilis*/*dehiscens* overlap), or (*b*) *G. dehiscens* ranges down to the *kugleri* zone, or (*c*) the ranges of both *kugleri* and *dehiscens* are such that they produce mutual overlap in the *dissimilis* zone in New Zealand.

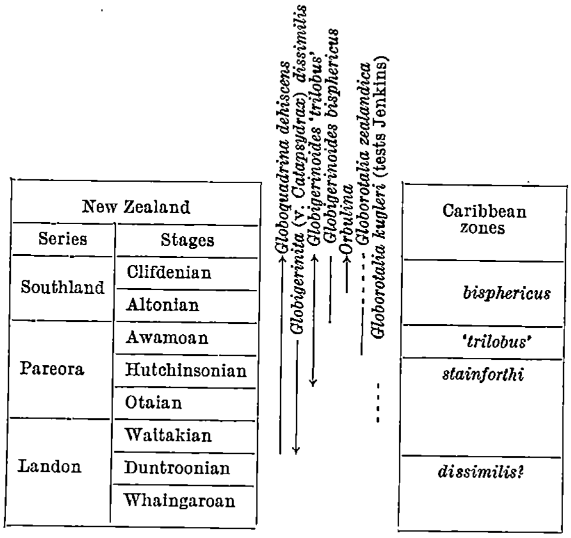

Fig. 1

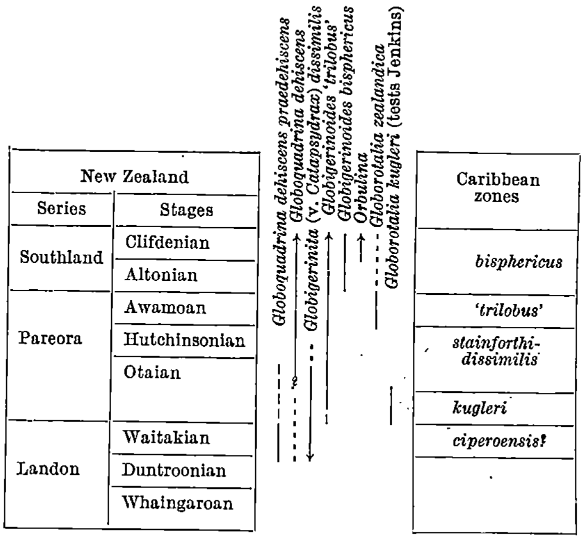

Fig. 2

Dr. Jenkins's simple assumption that his record of *G. kugleri* (unfigured) in samples attributed to the Otaian stage (but the age of which he does not confirm on faunal evidence) shows our suggested correlation to be "completely wrong" is clearly not warranted; instead his equally simple equation of the New Zealand stages and Trinidad zones in his Fig. 1[1], far from correcting a previous mid-Tertiary correlation, only poses more problems, the solution of which has yet to be advanced. In this context it is unfortunate that Dr. Jenkins, so quick to quote our suggested correlation, seems to have overlooked our conclusion in the same paragraph[2] that the faunas of the interval concerned were not sufficiently known to give more than an approximation.

The published occurrences and known ranges of the planktonic foraminifera[1–4] indicate a correlation on the lines set out in Fig. 1, in which, however, *Globorotalia kugleri* appears to be misplaced. It is possible, on the other hand, that Hornibrook's 1958[4] interpretation of *Globoquadrina dehiscens* includes the sub-species *G. dehiscens praedehiscens*, which is known to occur from the *ciperoensis* to low *stainforthi* zones in Trinidad, and which we have recorded from New Zealand[2] in samples believed to be Waitakian. Taking this into account, and accepting

Jenkins's record of *G. kugleri* as being from low in the Otaian, a scheme of correlation such as that set out in Fig. 2 would be possible: its confirmation by the observations of New Zealand workers would, of course, be necessary.

We note that his more recent work[5] has served to indicate that the type Aquitanian at Moulin de Bernachon, near Soucats, includes *kugleri* and/or *stainforthi* zones, as shown by the fauna of his sample from 3 metres above the exposed base of the section at that locality. This is especially interesting, since in 1962 we[2] demonstrated the presence of the *Globigerina ouachitensis ciperoensis* zone in the type Aquitanian and had, *inter alia*, assigned an Aquitanian age to the *kugleri* and *stainforthi* zones.

The foraminiferal faunas of the five younger samples from Aquitaine studied by Dr. Jenkins are relatively undiagnostic: of the nine identified species in them none is restricted to any particular zone or zones within the broad *kugleri-fohsi robusta* zonal interval and, with the exception of *Cassigerinella chipolensis* (only in sample 4), all range up to younger zones. The absence, from these poorly fossiliferous samples, of diagnostic, planktonic, zonal species tends to vitiate his correlation of these younger samples with the planktonic zonal scheme of Bolli; his very selective emphasis solely on the absence of one form (*Orbulina*) as being significant appears highly tendentious, as would be the suggestion that Jenkins's samples 5–8 are post *C. chipolensis*, and, therefore, post *fohsi robusta* zone[3], an equally valid assumption on the inadequate evidence!

Further work on the Tertiary planktonic Foraminifera is still required to clarify their zonal equivalences and in New Zealand to "establish a more accurate correlation of the Tertiary with rocks elsewhere".

F. E. Eames
F. T. Banner
W. H. Blow
W. J. Clarke

BP Research Centre,
Sunbury-on-Thames,
Middlesex.

[1] Jenkins, D. G., *Nature*, **200**, 1087 (1963).

[2] Eames, F. E., Banner, F. T., Blow, W. H., and Clarke, W. J., *Fundamentals of Mid-Tertiary Stratigraphical Correlation* (Camb. Univ. Press, 1962).

[5] Jenkins, D. G., *Cushman Found. Foram. Res. Contrib.*, **15**, 28 (1964).

In a previous communication[1] I provided evidence for correlating at least part of the Otaian Stage rocks in New Zealand with the *Globorotalia kugleri* zone of Trinidad and concluded that Eames *et al.*[2] had incorrectly correlated the Waitakian–Awamoan Stages with the *Catapsydrax stainforthi* zone of Trinidad.

After the discovery of *Globorotalia kugleri* Bolli from the North Auckland rocks, specimens were sent to Dr. H. M. Bolli for examination. He confirmed the identification in a private communication and it was then decided to publish the information. This should satisfy Eames *et al.*, who suggest in their reply that *G. kugleri* has been misidentified.

Eames *et al.* have apparently missed a previous publication by me[3] in which I attempted to explain the discrepancy in the stratigraphic ranges of *G. dehiscens* between Australia and Trinidad. In Australia[3] and New Zealand[5] the initial stratigraphic appearance of *G. dehiscens* is well before that of *G. trilobus*, whereas in Trinidad Bolli[6] records its initial appearance after that of *G. trilobus* and *G. kugleri*. It is assumed that the initial appearance of *G. trilobus* was simultaneous in the two areas (that is, within the range of *G. kugleri*) and that *G. dehiscens*, which was first described from the Miocene rocks of Australia, originated in the Australasian region and later spread into the Trinidad area.

The quadrate nature of the early form of *G. dehiscens* from Australia, soon after its initial appearance, has already been illustrated[3].

In a more recent publication Blow and Banner[2] have suggested that *G. praedehiscens* was the ancestor of *G. dehiscens*. This hypothesis is difficult to follow because *G. dehiscens*, which is a much more quadrate species, existed in Australasia at the time its supposed ancestor, *G. praedehiscens*, existed in Trinidad. Therefore, the initial appearance of *G. dehiscens* should not be used in any attempt to correlate the Australasian rocks with the Trinidad sequence.

In their reply Eames *et al.* have had two further attempts at correlating the New Zealand Stages with the Trinidad zones. It is noted that in their original discourse Eames *et al.*[2] stated "but we know from our own observations that *G. trilobus* occurs at the base of the Pareora and ranges up" and this fact is repeated in their reply (Fig. 2). The exact locations of these basal Pareora rocks in New Zealand need to be published so that they may be examined for '*G. trilobus*' by other workers.

Recent detailed investigation by Mr. N. de B. Hornibrook (personal communication) on New Zealand species has now shown that: (1) *Orbulina suturalis* (Blow emend, 1956)[4] starts at the base of the Lillburnian Stage and not at the base of the Clifdenian Stage as previously published[5]; (2) The level of extinction of *G. dissimilis* in New Zealand is still uncertain because it occurs rather sporadically. A previous record of *dissimilis* in the Altonian Stage[5] was based partly on its occurrence in rocks which are now known to be Otaian. The New Zealand Geological Survey has only one or two records of *dissimilis* in rocks definitely of post-Otaian age, but they are in fault zones and the specimens are possibly allochthonous; (3) The one known occurrence of *G. insueta* in New Zealand is near to the boundary of the Altonian–Clifdenian Stages in Hawkes Bay. An up-to-date range chart is given of 6 species of planktonic Foraminifera in the New Zealand rocks and a correlation is attempted with the Trinidad zone (Fig. 1). It should be noted that these ranges are based on the work of the New Zealand Geological Survey and differ from those given by Eames *et al.* in their reply (Figs. 1 and 2).

It is gratifying to note that Eames *et al.* in their reply have not reasserted the "considerable disconformity" originally proposed by them between the Duntroonian and Waitakian Stages[2]. The overall faunal succession of planktonic Foraminifera in New Zealand from this interval shows no evidence for this "considerable disconformity".

My recent remarks[7] concerning the post-Burdigalian entry of *Orbulina* in the European Tertiary rocks were intended to be tendentious, as Eames *et al.* suggest. The conclusion that "the initial appearances of *Globigerinoides bisphericus* Todd – *Orbulina universa* d'Orbigny lineage

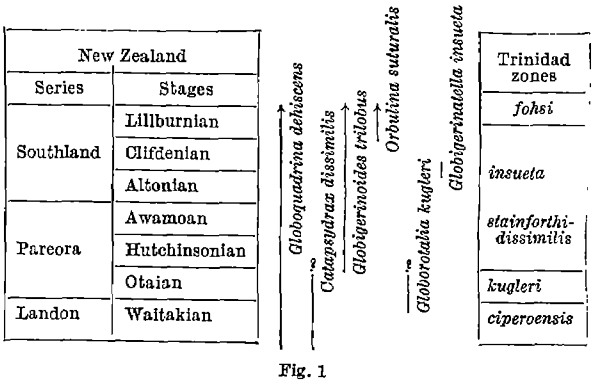

Fig. 1

must occur in post-Burdigalian rocks"[7] was reached after an examination of the type Aquitanian–Burdigalian planktonic foraminiferal fauna. Eames *et al.* state that the type samples are poorly fossiliferous, but this is not true. More than 100 specimens of planktonic Foraminifera have been extracted from each of the 5 youngest samples and the uppermost Burdigalian sample has innumerable planktonic foraminiferal specimens.

My "more recent work" on the type Aquitanian–Burdigalian fossils was undertaken in order to try and break the deadlock of opinion regarding the entry of *Orbulina* in European rocks which has retarded efforts at mid-Tertiary stratigraphic inter-continental correlation. The 'British School'[2] advocate the entry of *Orbulina* in the Upper Aquitanian and the "Continental School"[8–10] have apparently proved its entry in the Helvetian–Tortonian.

If Eames *et al.* maintain that the initial stratigraphic appearance of *Orbulina* occurs in the Upper Aquitanian, then more convincing evidence must be presented to substantiate this theory. If *Orbulina* were found in the type Upper Aquitanian–Burdigalian rocks it would pose the problem of the double entry of the lineage in European Miocene rocks and two well-separated *Orbulina* datum lines.

OCEANOGRAPHY

Evidence of a South Equatorial Countercurrent in the Atlantic Ocean in July 1963

AN eastward-flowing current of speeds of 4–7 cm/sec has been indicated in the Atlantic Ocean between 5° and 12·5° S. at about 14° W. longitude.

The evidence lies in the calculations of geostrophic flow at the sea surface with respect to the 1,000-decibar surface. The results for these calculations were collected during June 29–July 7, 1963, aboard the *Argo* on the seventh leg of the *Lusiad* expedition. A line of 13 oceanographic stations was made extending from 14° 54·5′ S., 019° 22′ W. to 05° 0′ N., 012° 39·5′ W. It is the first such section made across the equator in that season. The eastward flow between 5° S. and 12·5° S. averaged 4·5 cm/sec; the greatest speed of the eastward flow was about 7·4 cm/sec and was observed between the two stations at 12·5° S. and 10° S.

Flow to the east at this latitude is not indicated by any of the various atlases in any season[1,2]; instead, the flow in the area south of 6° S. is indicated as westward but very much weaker than that in the area north of 6° S. (ref. 1). It is not impossible that a weak eastward flow (4–7 cm/sec) could prevail in this season in all years without being detected from the ordinary set and drift observations. The set from such a current might easily be masked by the effect of the south-easterly trade winds that average more than Beaufort Force 4 (5·5–8 m/sec) in June and July[3]. Furthermore, the major shipping routes do not cross this area, and the few transits are on nearly north–south courses[4]; vessels would spend only a short time in the area of this eastward flow; they would be subject to a total current-drift of only about 7·8 km even if they required 48 h to cross the area. This is within the error of celestial navigation, and is probably smaller than the effect of the winds in that area.

There is no other sort of evidence available to examine the existence of this current. The other hydrographic data in the area are few and isolated and are not enough to confirm or deny such a current[5]; those measurements of density that lie near the *Argo* data are in agreement with them, however, and suggest that the *Argo* was not observing an unusual condition. It is interesting that this easterly flow was observed at the same season when the (North) Equatorial Countercurrent prevails in the Atlantic, and at the same season that the South Equatorial Countercurrent has been most clearly observed in the Pacific[6].

CHEMISTRY

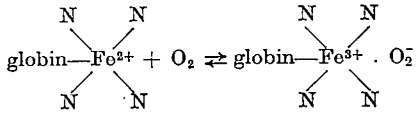
Nature of the Iron–Oxygen Bond in Oxyhæmoglobin

J. J. WEISS[1] has proposed that oxyhæmoglobin is a hæmoglobin peroxide, with the iron atom in the ferric state and the oxygen molecule present as an O_2^- ion, which is then taken up in the co-ordination shell of the ferric ion. He states that such an assumption accounts for the properties of oxyhæmoglobin.

Oxyhæmoglobin is, however, diamagnetic[2], and the generally accepted definition of oxidation number[3] requires that the iron atom in any diamagnetic molecule or complex containing one iron atom (no iron–iron bond) has an even oxidation number. It is accordingly not possible for an iron atom in oxyhæmoglobin to be described as ferric (oxidation number +3) unless a definition of oxidation number different from the usually accepted one is used.

The problem discussed by Weiss, the nature of the iron–oxygen bond in oxyhæmoglobin, was given a thorough discussion by me in two communications published about 15 years ago[4,5]. It is now possible to amplify the discussion somewhat, in part because of further development of the theory of the chemical bond[6] and in part because of the increased knowledge about the structure of oxyhæmoglobin and related molecules that has been obtained by the X-ray diffraction investigations of Kendrew[7] and Perutz[8].

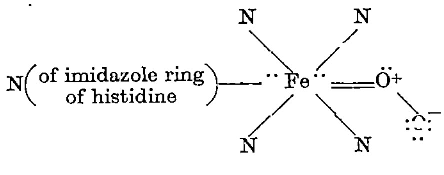
Weiss has illustrated his proposal by writing the following equation:



$$\text{globin—}\overset{\text{N}\ \ \text{N}}{\underset{\text{N}\ \ \text{N}}{\text{Fe}^{2+}}} + O_2 \rightleftarrows \text{globin—}\overset{\text{N}\ \ \text{N}}{\underset{\text{N}\ \ \text{N}}{\text{Fe}^{3+}}} \,.\, O_2^-$$

In the formula at the right, the dot represents not an electron but some sort of bond.

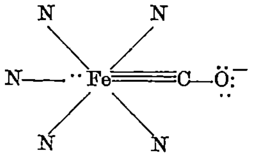
The structural formula which I proposed for oxyhæmoglobin[4,5] is the following:

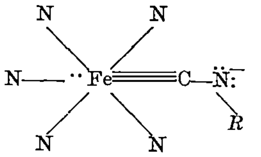


In this structural formula the iron atom is shown as forming a double bond with the first oxygen atom, which forms a single bond also with the second oxygen atom. (The iron atom then has two unshared electron pairs in its outer d^5sp^3 shell.) There is a formal charge $+1$ on the first oxygen atom and a formal charge -1 on the second oxygen atom. The difference in electronegativity of iron and oxygen is 1·7, which corresponds to 51 per cent of ionic character[9]. The electric charge assigned to the first oxygen atom is accordingly reduced to 0, whereas that of the outer oxygen atom remains -1. Except for the outer oxygen atom, the assigned structure is accordingly in good agreement with the principle of electroneutrality[10].

The negative charge assigned to the outer oxygen atom of oxyhæmoglobin can now be accounted for by the structure of myoglobin, as determined by Kendrew[7]. In the myoglobin molecule there is a residue of histidine adjacent to the iron atom on one side of the hæm group, and another residue of histidine constrained by the configuration of the polypeptide chain to a position a few Ångströms removed from the iron atom on the other side of the hæm. These two residues of histidine are those that were proposed originally by Conant[11], in order to account for the observed hæm-linked acid groups of hæmoglobin, and their positions relative to the iron atom are those postulated by Coryell and Pauling[12] in their detailed discussion of the mechanism of change in acid strength of hæmoglobin on oxygenation. It has been pointed out that the positive electric charge of the imidazolium side-chain of the second histidine residue probably serves, through its electrostatic interaction with the iron atom, to stabilize the bipositive state and assist in preventing oxidation of hæmoglobin to ferrihæmoglobin[13]. We see, also, that for oxyhæmoglobin the structure assigned above places an oxygen atom with a negative charge in close approximation to the positively charged imidazolium group and, indeed, in such a position as to permit hydrogen bonding with the negatively charged oxygen atom, thus further stabilizing the structure.

Similar structures, involving iron–carbon double bonds, were formerly assigned to carbonmonoxyhæmoglobin and the ferrohæmoglobin alkylisocyanides[4,5]. We may now recognize, however, that the arguments of the preceding paragraph strongly suggest that these molecules have structures in which the iron atom forms a triple bond with the carbon atom, and the outer oxygen atom or nitrogen atom has a negative electric charge:





I conclude that oxyhæmoglobin and related hæmoglobin compounds are properly described as containing ferrous iron, rather than ferric iron, that their electronic structure involves essentially the formation of a double bond between the iron atom and the near-by oxygen atom in oxyhæmoglobin (with the iron–oxygen–oxygen bond angle about 120°) and a triple bond to the carbon atom in carbonmonoxyhæmoglobin and the hæmoglobin alkylisocyanides (with iron–carbon–oxygen or nitrogen bond angle 180°). The iron–oxygen and iron–carbon interatomic distances in these compounds are predicted to have the values corresponding to these multiple bonds.

The essence of my suggestion was that there is a charge transfer from the hæmoglobin to the oxygen molecule, that is, some delocalization of one of the d-electrons of the ferrous towards the oxygen. This was meant as a starting approximation, the details to be settled by some physical measurements concerning the electronic structure. There are no obvious grounds why the resulting structure could not be diamagnetic. If this would not agree with a certain conventional definition of oxidation number then this would only show that this definition is no longer useful in this case. This is perhaps not surprising, because the O_2^- ion has itself an unpaired spin unlike the common anions such as OH^-, CN^-, which are all diamagnetic. This does, therefore, involve the more complicated problem of the interaction of the two magnetic ions when they come close together.

The charge-transfer complex and the structure proposed by Prof. Pauling have two prominent features in common as, according to Pauling, there also is (1) a charge of -1 on the oxygen, and (2) the iron–oxygen bond has a large percentage of ionic character. The difference lies essentially in the disposition of the third positive charge, which Pauling does not associate explicitly with the iron. It might be expected, in any event, that there will be some delocalization of the positive charge over the porphyrin ring. It will be of interest to see whether Prof. Pauling's much more specific proposals can be confirmed.

The reasons for my suggestion were given previously[1], one of these being the observation that oxyhæmoglobin can act as a strong oxidizing agent; for this it would be difficult to give a simple explanation on the basis of the conventional structure.

Molecular Orbital Evidence for Weiss's Oxyhæmoglobin Structure

We have read with interest the recent paper by Weiss[1] concerning the electronic structure of oxygenated hæmoglobin. From a consideration of: (1) magnetic properties, (2) absorption spectrum and (3) acid dissociation constant of oxygenated hæmoglobin, Weiss has proposed that the iron has a $+3$ charge. Therefore, iron is essentially in the ferric state. His paper has prompted us to give additional evidence in support of his idea.

The charge on the iron atom can be derived from the coefficients of the molecular orbitals of the complex. The molecular orbitals used were calculated for a general examination of the structures and properties of oxygen metal complexes. The calculations included a total of 17 atomic orbitals with 18 electrons in these orbitals. The orbitals considered were the $2s$ and three $2p$ on each oxygen atom and the five $3d$, one $4s$ and three $4p$ orbitals on iron. The general method of the calculation is that of Ballhausen[2], but the details and a discussion of the results will be given at a later date. Equation 1 (ref. 3) was used to calculate the charge on iron:

$$q_j = \sum_r \sum_j n_r C_{rj}^2 + \sum_r \sum_j \sum_{i \neq j} n_r C_{rj} C_{ri} S_{ji}$$
$$q_{\text{atom}} = Q - \sum_j q_j \qquad (1)$$

where q_{atom} = the signed charge of the atom in question; Q = number of electrons on the unperturbed atom; q_j = electron density in the j^{th} atomic orbital; n_r = number of electrons in the r^{th} filled energy-level; C_{rj} = wave function coefficient of the j^{th} atomic orbital in the r^{th} energy-level; S_{ji} = overlap integral value between the i^{th} and j^{th} orbitals of the system. The index j is over the orbitals of the atom in question, whereas index i is over all the orbitals of the system. Index r denotes only the filled energy-levels.

The result of our calculation is $q_{\text{iron}} = +\,2{\cdot}02$ based on the Pauling structure[4] for oxygenated hæmoglobin. The Pauling theory of the oxygen–iron complex is that an electron pair (probably sp^2) is donated from oxygen to an empty d^2sp^3 orbital of iron as a normal octahedral chelate is formed. Then there is back donation from a $d\pi$ orbital of iron into a higher π_g orbital of oxygen. Essentially Weiss predicts that this back donation is quite large. If the first electron pair is shared equally between ferrous iron and oxygen, and if there is no back donation, the calculated charge would be $q_{\text{iron}} = +\,1$. However, if back donation is so large that the iron is essentially ferric, and if the first electron pair is again equally shared, q_{iron} would be $\sim +\,2$. Thus the calculated value of $q = +\,2{\cdot}02$ shows that back donation is very largely in agreement with the theory proposed by Weiss.

Sequence Specificity in Synthetic Polydeoxyribonucleotides

Kornberg has shown that enzymatic synthesis of polydeoxyribonucleic acids from mononucleotides is possible even in the absence of a primer DNA molecule[1,2].

When mixtures of the two deoxyribonucleoside-5′-triphosphates, the heterocyclic bases of which were thymine and adenine, were used, Kornberg found that the polynucleotide formed after an initial time-lag was copolymer (Poly dAT) in which the bases alternated[1]. When the same procedure was carried out with the corresponding nucleotides containing the bases, guanine and cytosine, the product was a mixture of the two homopolymers, Poly dG and Poly dC, not always in equal amounts.

In both cases, in which exactly equimolar amount of the two mononucleoside triphosphates were used, there was evidence for double helix formation with base-pairing of the Crick–Watson type[2].

In order to determine how far this sequence specificity is a result of enzyme stereochemistry or simply a result of the molecular configurations of the nucleotides themselves, we have repeated the polymerization using equimolar amounts of the thymine and adenine deoxyribonucleoside-5′-phosphates, the thymine derivative being labelled with phosphorus-32 and a chemical condensing agent (di*cyclo*-hexylcarbodi-imide)[3].

In syntheses leading to deoxyadenosine polynucleotides, Khorana found it necessary to acylate the 6-amino group of the purine[4]. In our work, however, we have avoided the use of this blocking group in order that the molecular configurations should be as close as possible to those in the unprimed enzymatic synthesis. Parallel experiments are planned with systems incorporating the acylated nucleotide to determine the influence of these protecting groups on the sequence specificity.

The nearest neighbour analysis method was used on the polymeric product which had been freed from small molecules by dialysis and afterwards degraded by the action of spleen phosphodiesterase and micrococcal DNase producing nucleoside-3′-phosphates. Thus the labelled phosphate which enters the polymer as thymidine-5′-phosphate appears in the hydrolysate as the 3′-phosphate of the nucleoside which was next to the thymidine in the polymeric chain.

The nucleotides were separated by paper chromatography; the spots were cut out and their activity measured.

If homopolymers are formed (for example, of the Poly dG–Poly dC type), all the activity should be found in the originally labelled nucleoside, thymidine, in the form of the 3′-phosphate. If, however, there is co-polymerization with a perfect alternation of bases, all the activity should be transferred to the initially unlabelled nucleoside, deoxyadenosine. Co-polymerization with a random sequence of bases should lead to both nucleoside-3′-phosphates having equal labelling.

In our experiments, we have found that the polymeric material, on degradation, yields a mixture of nucleoside-3′-phosphates in which approximately 20 per cent of the labelled phosphate has been transferred to the 3′-position of the deoxyadenosine.

Thus it is clear that there is some co-polymerization, but that there is neither a perfectly alternating sequence nor a completely random sequence.

Further experiments, in progress, using labelled deoxyadenylic acid should indicate how far the result may be explained by loss of deoxyadenylic acid from the polymerizing system as a result of the unprotected amino group.

We thank the Department of Scientific and Industrial Research for a grant for equipment and Unilever, Ltd., for a research studentship (G. R. B.). We also thank the Radiochemical Centre, Amersham, for a gift of ^{32}P-labelled thymidine-5′-phosphate.

A Flow Method for Determining the Thermal Conductivity of Gas Mixtures

The thermal conductivity of a mixture of two gases does not, in general, vary linearly with the composition of the mixture. For two gases of similar molecular weight the degree of non-linearity is small, while for systems of widely different molecular weight, linearity rarely extends beyond 0·05 mole fraction from either pure component.

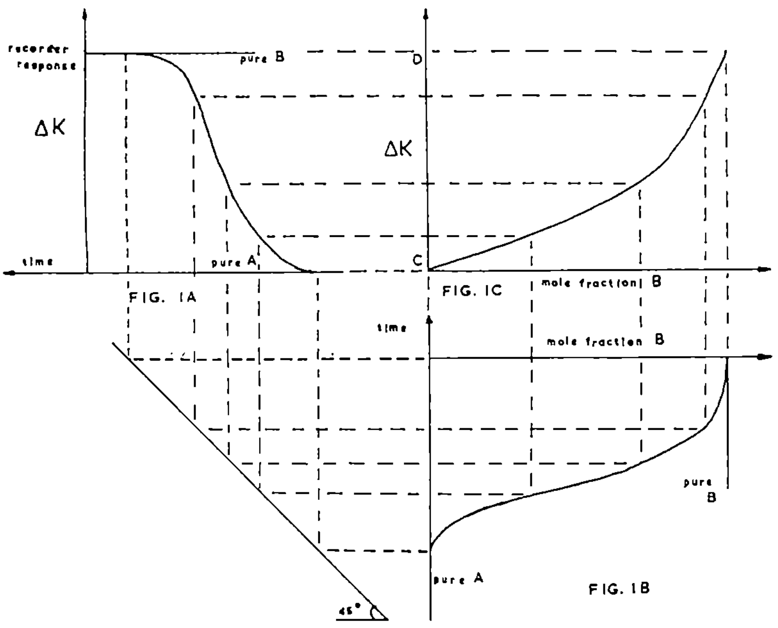

Fig. 1

Mixtures containing appreciable amounts of both components are of interest experimentally, and in the theory of transport phenomena. The collection of such conductivity data is usually time-consuming.

During some experiments on the dispersion of gases in laminar flow through a circular tube, anomalous results were obtained, as expected, for pairs of gases of widely differing thermal conductivity when a katharometer was used to determine the tracer gas concentration profile. It is possible, however, to explain quantitatively the discrepancies between the theoretical predictions and the experimental results in terms of the non-linearity described previously. This provides a method of obtaining, in a few minutes, a continuous curve of the variation of thermal conductivity with composition.

Assuming that the operation of the katharometer depends only on thermal conductivity[1], and that the recorder trace is a linear representation of the thermal conductivity difference, ΔK, then the introduction of a step change from gas A to gas B will produce a plot of the thermal conductivity of the mixture, ranging from pure A to pure B, as a function of time. Such a trace, which will be a distorted concentration profile, is given diagrammatically in Fig. 1A.

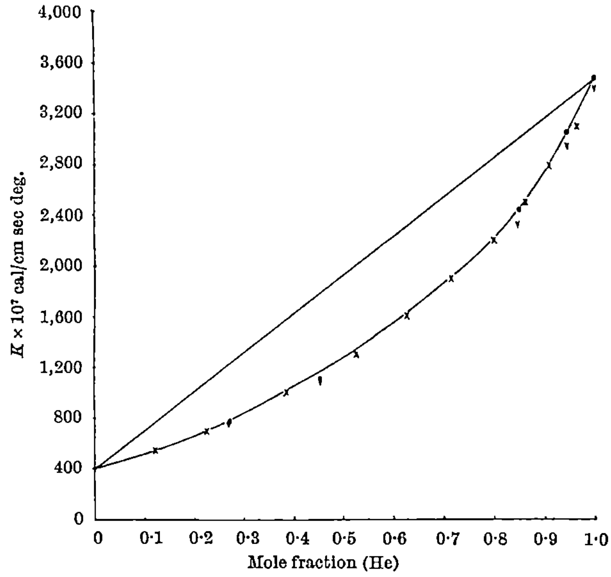

Fig. 2. Thermal conductivity of argon/helium mixtures. ×, this work; ●, calculated (ref. 5); V, experimental (ref. 5)

For a given mean velocity, $\bar{u}$, which may be found from the volume flow rate, and the molecular diffusion coefficient for the system, D_{AB}, the true concentration profile corresponding to Fig. 1B, may be calculated from equations (1) and (2), since for a tube, radius a, the effective dispersion coefficient is D_e (ref. 2).

$$D_e = D_{AB} + \frac{a^2\bar{u}^2}{48D_{AB}} \qquad (1)$$

This has been verified by us to hold to a high order of accuracy, and details will be published shortly. The mean concentration across the tube, as a function of time, t, is:

$$\frac{C_m}{C_0} = \frac{1}{2}\left\{1 - erf\left[\frac{L - \bar{u}t}{2\sqrt{D_e t}}\right]\right\} \qquad (2)$$

when the tracer has travelled a length L.

These equations imply that the value of the molecular diffusivity is independent of concentration. To a first approximation this is true.

Equation (2) may be plotted on the same time-scale as the recorder trace, as in Fig. 1B. By projection, given by the broken lines, as many points as may be required can be found for the curve of thermal conductivity against composition (Fig. 1C).

The method was tested experimentally by injecting a step change of helium into flowing argon. The apparatus consisted of a straight steel tube 17·29 m long, mounted horizontally in a room maintained at 19·5° ± 0·5° C. A twin cell katharometer, forming part of a Wheatstone bridge, monitored the concentration profile. The use of two hot wires eliminated the effect of small velocity fluctuations, and presented, on the recorder, the profile in terms of the difference ΔK, in thermal conductivity between carrier gas A with tracer B, and pure A. The katharometer is specially designed to have a negligible volume (0·5 ml.), and to present as little disturbance to gas flow as possible. Tracer injection is carried out by means of an 'O' ring, annular valve[3].

The results are given in Fig. 2, in which are also plotted theoretical values, and some experimental results of Wachsmith[4]. The literature values refer to 0° C, whereas the experimental values were obtained at 20° C. Since the difference between the thermal conductivities of the pure components at these two temperatures is relatively slight, the conductivities of the pure components at 0° C were assigned (for purposes of comparison) to positions C and D in Fig. 1C.

It can be seen that the degree of fit is good. In an accurate determination, the thermal conductivities of the pure components would have to be known at the mean system temperature.

Acid-labile Ribose as an Indicator of Ribonucleic Acid Base Composition

The lability to acid of purine ribomononucleotide N^9-glycosidic linkages, as opposed to the stability of pyrimidine ribomononucleotide N^3-glycosidic linkages, is well documented (for example, ref. 1). It has, however, been noted that the latter linkage is not completely resistant, in the cases of cytidylic and uridylic acids, under the conditions of the Bial reaction of their pentose moieties with orcinol[2].

The acid lability of purine mononucleotides has been used to estimate the purine/pyrimidine ratios of yeast whole-cell ribonucleic acid[3] by recalculation from the molar ratios of acid-labile ribose/nucleotide phosphorus. The validity of this method depends on the freedom of the examined RNA from extraneous, non-nucleic acid phosphorus and the hydrolytic release only of purine ribose and its reaction with orcinol. The first condition was satisfactorily achieved; an examination of the second is reported here.

Approximately 1 mM aqueous solutions of mixed 2′ and 3′ isomers of GMP, AMP, CMP and UMP (Sigma) were prepared. Quadruplicate aliquots of 1 ml. were used in estimating acid-labile ribose by a modification[3] of the method of Ceriotti[4]. The results, presented as the molar ratios of acid-labile ribose/orthophosphate (estimated by the method of Boltz and Mellon[5]), are shown in Table 1.

Table 1. MOLAR RATIOS OF ACID-LABILE RIBOSE TO ORTHOPHOSPHATE IN RNA MONONUCLEOTIDES

Nucleotide	Molar ratio Expected	Found
GMP	1·0	0·985 ± 0·011
AMP	1·0	1·000 ± 0·020
CMP	0	0·0097 ± 0·003
UMP	0	0·062 ± 0·003

Under the conditions of ribose estimation (final concentration of hydrochloric acid, 5 N) hydrolysis of GMP and AMP is virtually complete. Only UMP of the pyrimidine nucleotides contributed significant colour.

Acid-labile ribose was similarly estimated in artificial mixtures of the four nucleotides. Ribose/phosphate ratios, recalculated to purine/pyrimidine ratios, are shown in Table 2. 'Expected' ratios were based directly on molar proportions of nucleotides, given 100 per cent purine mononucleotide hydrolysis and no pyrimidine mononucleotide hydrolysis, while 'corrected' ratios included allowances for 98·5, 100, 1 and 6 per cent hydrolysis, respectively, for GMP, AMP, CMP and UMP.

Table 2. PURINE/PYRIMIDINE RATIOS OF ARTIFICIAL MIXTURES OF RNA MONONUCLEOTIDES

Molar proportions				Purine/pyrimidine ratio		
GMP	AMP	CMP	UMP	Expected	Corrected	Found
24·7	26·0	26·8	22·5	1·03	1·08	1·08
29·6	29·2	20·4	20·7	1·43	1·49	1·49
24·0	21·0	25·0	30·0	0·82	0·88	0·88

Agreement between corrected and experimental values of 'purine/pyrimidine' ratios was good. Consistent overestimate of the true value, of the order of 0·05–0·06 unit, is apparent, so that precise estimates of purine/pyrimidine ratios must still depend on separation of the four nucleotides in hydrolysates of RNA. However, the method provides a useful guide before the more time-consuming separations are undertaken.

Oxidation of β-Carotene by Hydroperoxides

It is generally believed that bleaching of β-carotene concurrent with lipoxidase catalysed oxidations of fixed oils occurs by reaction with intermediates of the autoxidation process. This view, which appears to be based originally on the observation that loss of colour proceeds only very slowly in the presence of previously peroxidized fat[1], has led to a general conclusion that hydroperoxides do not oxidize carotenoids readily[2]. Recent investigations of the action of tetralin hydroperoxide, concerned with product analysis, have again emphasized that the reaction proceeds only very slowly[3].

We have now been concerned with rates of oxidation of β-carotene by *tert*-butyl hydroperoxide over a series of concentrations—using hydroperoxide/pigment molar ratios of 5–200/1.—and find that loss of β-carotene occurs in a regular manner for each amount of hydroperoxide used.

To 0·1 per cent (0·0186 mole per cent) solution of β-carotene in chloroform (2 ml.) was added the required amount of pure *tert*-butyl hydroperoxide and the mixture, diluted to constant volume (2·5 ml.) with more chloroform, kept at 25° in the dark. The small flasks were flushed with nitrogen and access of oxygen prevented so far as possible during handling. Residual β-carotene was separated from oxidation products by chromatography on alumina using light petroleum (b.p. 60°–80°) for development, and estimated spectrophotometrically. Results are illustrated in Fig. 1.

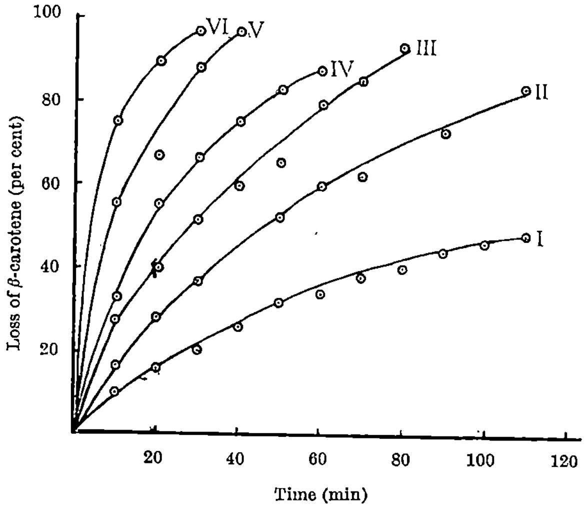

Fig. 1. Oxidation of β-carotene by *tert*-butyl hydroperoxide in chloroform at 25°. Moles hydroperoxide per mole of pigment: I, 5; II, 10; III, 20; IV, 50; V, 100; VI, 200

It will be observed that even with the lowest concentration of hydroperoxide used (5 molar ratio), loss of β-carotene is recognizable after 10 min. Indications are that the initial reaction is first order with respect to the β-carotene but stepwise increase in the concentration of hydroperoxide used does not lead to a proportional increase in the rate of loss of pigment. Although all solutions ultimately are completely bleached, due to the continued action of hydroperoxide on the initial products, nevertheless the early losses of β-carotene are masked by a darkening and change in shade of colour of the solution. This is easily visible to the eye, but the trends of change are better revealed by the Lovibond readings of Table 1.

While the intensity of colour precludes use of the readings other than as indicating the general trend of change, nevertheless they provide a more adequate representation of the process than vaguer descriptions of appearance visually. In particular the introduction, rise and gradual subsequent fall in blue components should be noted.

Table 1. LOVIBOND TINTOMETER READINGS DURING OXIDATION OF β-CAROTENE BY *Tert*-BUTYL HYDROPEROXIDE (1/20 MOLAR RATIO) IN CHLOROFORM AT 25°

Time (min)	Lovibond units Yellow	Red	Blue	Time (min)	Lovibond units Yellow	Red	Blue

Over the first 60 min there is an increase in red and yellow components together with the introduction of a not inconsiderable blue component, which is reflected by a change in visual appearance to slight off colour from the cleaner reddish-yellow of the original solution. As oxidation proceeds over the next 60 min a change in the balance of colour occurs, with increases, at a reduced rate, in the yellow and blue components coupled with loss of red. At this stage the solution darkens considerably to the eye, reflecting the continued increase in blue values. The outstanding feature of the third hour is the maintained loss of red units now accompanied by loss of blue, that is, visually the solution becomes a cleaner yellow of reduced overall depth of colour.

It is not unlikely, therefore, that similar effects in fats may have been responsible for early statements, which appear to be based on colour observation alone, suggesting that no immediate reaction occurs.

Explanations offered for the ultimate bleaching action of linoleate hydroperoxide appear in the main to have been concerned with the initiation of radical decomposition[4] without consideration of the possible superimposed more direct effects of low concentrations in the early stages of the process. Present results therefore indicate that, for oily solutions, more attention might be given to the possible role of preformed fatty acid hydroperoxide in directly attacking β-carotene.

BIOCHEMISTRY

A New Steroid found in the Urine of Children but not Adults

DURING a longitudinal investigation of the changes with age in steroid excretion in healthy children, we have found a new steroid substance[1]. It was present in 11 out of 19 healthy children aged 8–12 years; in all of 7 healthy 3-year-old children; and in none of about 100 adult men and non-pregnant women. Twelve of the 8–12-year-old children have been examined repeatedly at six-monthly intervals, for 18 months–2 years. Six were initially excretors and six non-excretors, and none showed any change in status. Four adults with Cushing's syndrome were all non-excretors, but both of two pregnant women tested excreted the substance. Two children with the rare disease of lipodystrophy and accelerated growth and one 3-year-old child with progeria showed a markedly greater excretion than anybody else we have seen.

The substance does not appear to be dietary in origin since it was excreted by three children under strict dietary control in the metabolic ward of the Hospital for Sick Children. Furthermore, we have followed two non-excretors and one excretor during ACTH response test given for other reasons. Both non-excretors produced the substance on stimulation together with a general increase in oxosteroids and corticosteroids. The excretor failed to respond to ACTH, and the excretion of the substance remained unaltered. It seems, therefore, that this steroid may be regarded as a normal constituent of healthy children's urine, at a certain stage of growth.

The substance was excreted as a glucuronide salt only. After extraction of the urine, hydrolysis with β-glucuronidase and preliminary separation on Whatman 3 *MM* paper, it appeared as a Zimmermann-staining spot near to the 11-oxo-17-ketosteroids in the modified two-dimensional system of Edwards[2].

In the modified Bush *B*3 system[3] it ran with 11-hydroxyandrosterone but was distinguished from it by absorbing ultra-violet light. It was eluted from the modified *B*3 run on No. 2 paper, as used in our usual procedure[4], and isolated by re-running on a slower-moving chromatogram for 24 h. It was then purified by passage through a 'Sephadex' column[1].

It then showed the following reactions: (1) under ultra-violet light a peak at 223 mμ; (2) blue colour with Zimmermann reagent; (3) ultra-violet fluorescence when treated with sodium hydroxide and a small amount of triphenyl tetrazolium chloride; (4) after reaction with 20 per cent orthophosphoric acid a weak pinkish colour after dipping, and strong ultra-violet fluorescence; (5) a pink colour when refluxed with selenium dioxide in acetic acid and benzene (Fieser reaction)[5]; (6) sulphuric acid spectra in various modifications[6–8] gave peaks at 410, 408 (470) and 370 (480) mμ respectively whereas an authentic sample of a Δ^5-3-hydroxy compound (dehydro*epi*androsterone) gave peaks at 410, 408 (490) and 390 (470) mμ (the figures in parentheses indicate minor peaks); (7) Menini–Norymberski[9] reaction with *tert*-butyl chromate on paper[10] positive with strong ultra-violet fluorescence; (8) reaction with phosphomolybdic acid gave a similar speed to dehydro*epi*androsterone. Reactions 5–8 indicate that the substance has a Δ^5 structure: (9) R_M value of $+0 \cdot 72$ on a modified Bush *B*3 system paper chromatogram (approximately equal to 11-OH-androsterone). R_M values of formates, acetates and propionates in several modified Bush *B*3 systems were compared with similar esters made from mono-, di- and tri-hydroxy reference steroids. From this it was evident that the substance contained one hydroxyl group, most likely at C3; (10) R_M of the acetate and its CrO_3 oxidant product and the $NaHCO_3$ hydrolysate of the oxidation product were all the same; (11) the infra-red spectrum (carried out by the Cambridge Instrument Co.) revealed the presence of single free OH group. Reactions 9–11 indicate a single hydroxyl group, at C3: (12) reaction with blue tetrazolium reagent positive, but much slower than cortisol, deoxycorticosterone or compound *S*; (13) positive reaction with silver diamine reagent[11]; (14) reaction with 2,4-dinitrophenyl hydrazine and thiosemicarbazine was positive; (15) after treatment with Girard reagent, the substance was recovered from the ketonic fraction with R_M value unchanged; (16) reaction with hydroxylaminic acid reagent and $FeCl_3$ gave a pink colour; (17) Schiff's reaction positive; (18) infra-red absorption at 1,676 cm^{-1}; reactions 12–18 strongly suggest an aldehyde group, at C17.

The ultra-violet spectrum and selenium dioxide reaction suggest a diene structure, and treatment with osmium tetroxide gave a compound with a much larger R_M value than the original substance. The placement of the second double bond must await further study of synthetic compounds, but the infra-red spectrum and ultra-violet absorption suggest that it may be at C16. Oxidation with CrO_3 and $NaBiO_3$ and reduction with a borohydride were not very successful. The first gave 'streaking' on paper, the second 'streaking' and several Zimmermann-reacting materials with R_M values of 0·72, 0·31 and −0·36 in modified Bush $B3$ system.

The pattern of the infra-red spectrum indicates a steroid structure. Though large numbers of reference standards including Δ^{16}-androsternol, 4-6-dienes, 16-OH-pregnenolone, Δ^{16} pregnenolone, 6-OH testosterone, 11-ketotestosterone, 2-OH testosterone, 7-keto and 7-OH dehydro*epi*androsterone, kryptogenin, diosgenin, 3β-ol-chol-5-enic acid were compared with the substance none of them showed an identical pattern.

From the results so far obtained, we may conclude that the new substance is probably a steroid with a hydroxyl group at C3, one double bond at C5, another possibly at C16, and an aldehyde group at C17.

The substances observed in the urines of new-born infants by Dr. Bierich[12] and Dr. Cathro *et al.*[13], may well be the same compound as ours. At present its physiological significance is unknown. Possibly it represents an intermediate or alternative product of the adrenal androgen system, characteristic of some or all children at a stage prior to the maturation of some unidentified enzyme system. As it seems likely to be something which occurs in children's urine, disappearing at some time, yet to be determined, before maturity, we suggest 'childhood steroid' as a strictly temporary descriptive label until its full chemical structure is known.

We thank Prof. I. E. Bush and Dr. R. W. H. Edwards for their advice, Prof. W. Klyne for a supply of reference steroids, Dr. Barbara Clayton, Dr. John Davis, Dr. Eades and Dr. D. Shaw for allowing us to study their patients, Dr. Chamberlin, of Merck, Sharpe and Dohme for a gift of ergosterol-D, Dr. B. W. L. Brooksbank for a gift of androst-16-en-3-ol, Mrs. Anna Cole for assistance and critical suggestions, and Mrs. A. V. Bagnall for the collection of urine specimens. This work was supported by a grant from the Medical Research Council.

Pure Chlorogenic Acid not Allergenic in Atopy to Green Coffee: a Specific Protein Probably is involved

Recent articles[1–5] have reported that chlorogenic acid (3-caffeoylquinic acid) is the principal allergen in green coffee, oranges, other fruits and vegetables, and castor beans. Figley and Rawlings[6] and Coulson *et al.*[7] have shown that apparent cross-reactions to green coffee and castor beans are due to traces of castor bean proteins present as a contaminant in commercial green coffee. Layton *et al.*[8] have shown that primary allergy to castor beans involves neither chlorogenic acid nor any other natural constituent of the coffee bean. Recent reports by Freedman, Sehon *et al.*[4,5] have reaffirmed their view of the allergenic nature of chlorogenic acid and of its involvement in atopic hypersensitivity to coffee, castor beans and oranges. Chlorogenic acid is a ubiquitous component of higher plants, and if it should prove to be an allergen then this becomes a matter of major concern to both medicine and agriculture.

We were conducting clinical and laboratory investigations on several hundred French patients with allergy to castor beans and had found 29 patients who showed strong skin reactions to green coffee. Hence, we decided to investigate this newly reported aspect of atopy to a common component of plant materials by utilizing the allergic serum transfer test in monkeys[8,9] and relating the results to the clinical tests on the serum donors.

50 g of green coffee beans were freed of dust by rinsing with cold water. The coffee was dried at room temperature and then ground in a coffee mill. The ground green coffee was extracted with 250 ml. of distilled water at room temperature; the lyophilized crude extract weighed 9·4 g. 2 g of the dried crude extract was dissolved in 40 c.c. of water and dialysed for 18 h through 23/32 Visking* seamless cellulose tubing against two changes of water of 500 c.c. each. The lyophilized diffusate weighed 1·57 g, and the non-diffusible 'retentate' weighed 0·4 g. Ultra-violet absorption spectra indicated that almost all the chlorogenic acid was in the diffusate, and very little in the retentate.

'Crude' chlorogenic acid was prepared from green coffee by the method of Sondheimer, Szymanski and Corse[10,11], which involves extraction of the green coffee with 70 per cent isopropanol (aq.) followed by several recrystallizations of the potassium caffeinate–chlorogenic acid complex. A sample of chlorogenic acid was also obtained from Nutritional Biochemicals Corporation*. Pure chlorogenic acid was prepared from the crude acid by counter-current distribution between ethyl acetate and 10 per cent sodium chloride (aq.) in a 200-tube counter-current distribution extraction apparatus.

Clinical skin-scratch tests were conducted on 200 French patients most of whom were allergic to castor bean dust and house dust. Twenty-nine of the patients tested showed a high degree of sensitivity (2+ to 4+ reaction)[8] to a 1 per cent solution of crude green coffee extract. None of the patients showed significant sensitivity to a 1 per cent solution of chlorogenic acid. We used blood sera from the 29 French patients, and Dr. S. O. Freedman of Montreal, Canada, provided sera from 12 of his coffee-allergic patients. All these coffee-allergic sera were tested in macaque monkeys by the allergic serum transfer tests of Layton[8,9]. The monkeys were intradermally sensitized in skin sites with all 41 of the French and Canadian sera. 48 h after passive sensitization the monkeys were given intravenous injections of Evans blue dye solution. Each was challenged at 20-min intervals by intravenous injections of 25-mg samples of each of the materials being tested for allergenicity, beginning with the most highly purified and ending with a 5-mg injection of the crude retentate of green coffee. The blue lesions (extravasation of dye) resulting from reaction between reagin and green-coffee atopen were evaluated and photographed in colour.

Of the French patients clinically tested with coffee components, all 29 reacted to crude extract of green coffee but none reacted to chlorogenic acid. In the passive transfer tests, none of the 41 reaginic sera reacted with chlorogenic acid purified by counter-current distribution. All the Canadian sera reacted with 25 mg of one preparation of crude chlorogenic acid, but few of the French sera reacted with this material. 25 mg of another sample of crude chlorogenic acid prepared in our laboratory caused all sera to react. When the passively sensitized animals were challenged with 25 mg of 8-h and 18-h dialysates

(diffusates) of green coffee there were no reactions; however, diffusate from a 72-h dialysis of green coffee caused reactions in one French and one Canadian serum-sensitized site. The 5-mg sample of non-diffusible retentate of green coffee contained very little chlorogenic acid, but caused all 41 sites to react strongly (3+ to 5+ lesions). Coffee beverage prepared from roasted coffee was found to contain considerable chlorogenic acid but to be non-allergenic when tested in the passively sensitized monkeys.

From these results of clinical tests and passive transfer in monkeys, it appears that the 12 Canadian patients, all of whom work with green coffee, are more sensitive than are the French patients whose sources of green coffee-sensitization are as yet unknown. The clinical tests clearly indicate that chlorogenic acid is not a significant factor in allergy to green coffee among the French patients. The passive transfer tests indicate that the atopic reagins of both the Canadian and French patients react primarily or exclusively with a higher-molecular-weight non-diffusible component of green coffee. This atopen is probably a protein. Chlorogenic acid is obtained from green coffee and most samples probably are contaminated by traces of protein from the coffee. Coffee beverage prepared from roasted coffee is non-allergenic.

Utilization of Adenine by a Mutant of *Candida utilis*

Previous work has shown that *Candida utilis* (strain *IMI* 23311) efficiently utilizes exogenous adenine for the synthesis of RNA[1]. During the course of subsequent investigations[2], fresh cultures obtained from the Commonwealth Mycological Institute were found to have undergone mutation. The mutant had a longer generation time than the original strain when grown in rich medium, and failed to grow satisfactorily under conditions used in tracer experiments. Since no culture afterwards supplied by the Commonwealth Mycological Institute was found to have the characteristics of the original strain, experiments were continued with *C. utilis* strain *NCYC* 321. This strain had been maintained since 1951 from an original culture of strain *IMI* 23311 (ref. 3) and was found to have similar growth characteristics to those of the original culture of strain *IMI* 23311 used in these laboratories. The mutant has now been found to differ from strain *NCYC* 321 with respect to the utilization of exogenous adenine, and it is desirable to record that strain *IMI* 23311 no longer has the metabolic characteristics of the organism used in our previous work.

C. utilis strain *NCYC* 321 had a generation time of 120 min under the conditions previously described[1]. Under the same conditions, the generation time of the mutant of strain *IMI* 23311 varied between 7 and 12 h. Growth of the mutant was somewhat stimulated by addition to the medium of biotin (0·01 mg/l.), thiamin hydrochloride (1 mg/l.) or myo-inositol (1 mg/l.), the generation time ranging from 3·5 h to 4·5 h under these conditions. Addition of all three of the above vitamins to the medium produced no greater increase of growth than that produced by each added singly and no precise growth requirement for the mutant can be given. Addition of the above vitamins to the medium did not stimulate the growth of strain *NCYC* 321.

Cells were allowed to grow logarithmically for one generation in presence of adenine labelled with carbon-14, collected, and RNA was isolated as previously described[1]. In cultures of *C. utilis* strain *NCYC* 321, 98·7 ± 3·6 per cent of the radioactivity of the added adenine was recovered in the RNA; in cultures of the mutant of strain *IMI* 23311 recovery amounted to only 37·6 ± 1·9 per cent. This was raised to 53·4 ± 0·87 per cent by addition of biotin, thiamin hydrochloride and myo-inositol to the medium, presumably due to the greater requirement for adenine under conditions of higher growth-rate.

Cells collected towards the end of logarithmic phase were suspended in buffer at *p*H 7·5 (ref. 4), and broken in the Mickle disintegrator. The cell-free extract was centrifuged at 0° at 20,000*g* for 1 h and aliquots of the supernatant (2 ml.) were incubated at 37° with ^{14}C-adenine (0·15 μc.; specific activity 0·15 mc./mg), tetrasodium fructose 1,6-diphosphate (0·3 ml., 10 per cent w/v) and protamine sulphate (30 μg). After varying intervals of time, enzymic reactions were stopped by the addition of 10 per cent (w/v) trichloroacetic acid and, after removal of protein by centrifugation, the supernatant was freed from trichloroacetic acid and submitted to paper electrophoresis at *p*H 3·5. Radioactive spots were located either by autoradiography or by means of the radioactive chromatogram counter (Baird and Tatlock, Ltd., London). Radioactive material was eluted from appropriate areas of the paper and identified by paper chromatography in two solvent systems. After incubation for 30 sec, highly radioactive spots corresponding to adenine and hypoxanthine were identified in extracts of both strains of *C. utilis*, no other radioactive materials being present on the paper. After incubation for 5 min or longer, extracts of strain *NCYC* 321 resulted in radioactive spots corresponding to adenosine and inosine in addition to adenine and hypoxanthine. With extracts of the mutant of strain *IMI* 23311, a radioactive spot corresponding to adenosine was produced after incubation for 5 min or longer, but no spot corresponding to inosine was identified up to incubation for 30 min. It was estimated that radioactivity as low as 0·05 per cent of that present in the adenine- or hypoxanthine-containing spots would have been detected by autoradiography under the conditions used.

These results indicate that, in both strains, hypoxanthine is the earliest recognizable metabolite of adenine. The absence of detectable amount of radioactive inosine from cell-free extracts of the mutant strain is believed to be due to its formation from hypoxanthine being blocked; the alternative explanation, namely, that inosine can be utilized more rapidly than it is formed, is not in agreement with the poor utilization of the radioactive adenine by this strain. On the basis of the present experiments, it cannot be decided whether adenosine and inosine arise directly from the corresponding bases or whether they are formed by dephosphorylation of nucleotides. In either event, it appears probable that the conversion of adenine into hypoxanthine is the first reaction in the major route in the utilization of exogenous adenine for RNA synthesis and that loss of ability to form nucleotides from hypoxanthine is responsible at least in part for the poor growth of the mutant of *C. utilis* in simple medium.

Some Physical Properties of Interfering Substances associated with the Alkaline Hydrolysis of RNA from Plant Leaf Tissue

Previous investigations[1] in our laboratory indicated that treatment of de-fatted, dechlorophyllized leaf tissue with alkali would hydrolyse the RNA into spectrophotometrically measurable nucleotides. Other studies[2] showed that RNA was preferentially eluted with 0·12 N hydrochloric acid from a column of 'Dowex 1–8X' on which mixtures of RNA and DNA had been adsorbed. This shortened exposure to alkali and recovery of RNA from mixtures of nucleic acid suggested the possibility of direct estimation of RNA in neutralized leaf hydrolysates by passage through a column of Dowex and subsequent elution with 0·12 N hydrochloric acid. Such eluates, however, invariably possessed greater absorption at 260 mμ than comparable material treated according to Diener and Lasheen[3]. The lower maxima/minima (*Mx*/*Mn*) ratios (A_{260}/A_{234}) for the neutralized material indicated that this higher absorbance was due to substances other than RNA. It was found that acidification of these alkaline hydrolysates followed by addition of an equal volume of ethanol and 2 drops of 1·0 M magnesium chloride would precipitate these substances absorbing at 260 mμ.

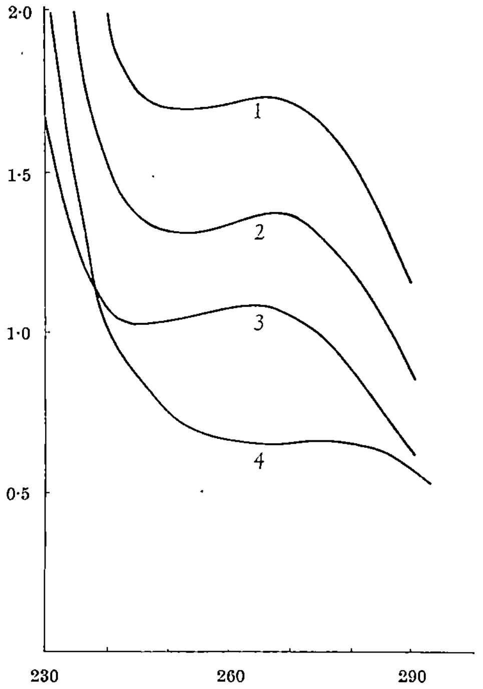

Fig. 1. Absorbance of 0·33 N potassium hydroxide digest. Area between curves 1 and 4, water-soluble impurities, *p*H 7·0; area between curves 2 and 4, 50 per cent ethanol soluble impurities, *p*H 7·0; area between curves 3 and 4, 50 per cent ethanol plus Mg^{++}-soluble impurities, *p*H 7·0; area between curves 4 and base, absorbance of hydrolysate adjusted, *p*H 5·0

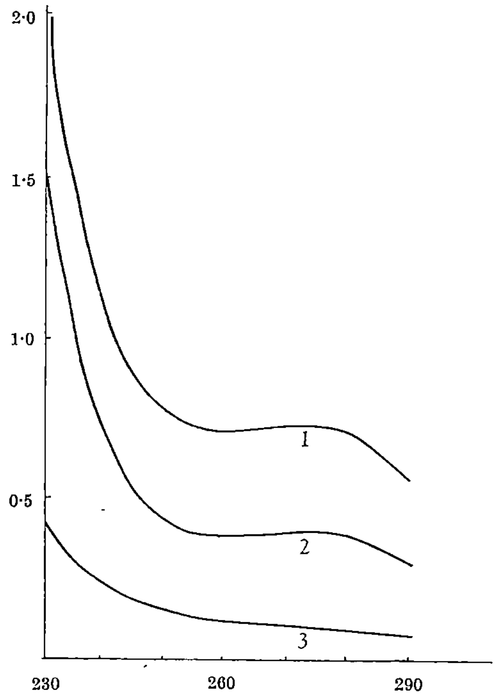

Fig. 2. Absorbance of impurities not adsorbed by 'Dowex' resin. Area between curves 3 and base, absorbance of acid alcohol impurities, *p*H 5·0; area between curves 1 and 3, absorbance of water-soluble impurities, *p*H 7·0; area between curves 2 and 3, absorbance of alcohol-soluble impurities, *p*H 7·0

Several portions of the hydrolysates, after removal of the extraneous material by centrifugation, were adjusted to *p*H's of 5·0, 6·0 or 7·0. Equal volumes of water, alcohol, and alcohol plus 2 drops of magnesium chloride were added to duplicates at each *p*H and stored for at least 2 h at 2° C. These were then centrifuged to remove the precipitated substances and brought to volume with water and then 10-ml. portions were passed through the column. After washing the column with 5 ml. of double distilled water, the RNA was eluted with 0·12 N hydrochloric acid. The results of a typical experiment are given in Table 1.

These data showed good reproducibility in the recovery of RNA for *p*H 5·0 for the treatments involving ethanol and ethanol plus magnesium chloride. *Mx*/*Mn* ratios for both treatments were greater than 2, values similar to those observed by Reddi[4] for solutions of tobacco mosaic RNA. Nearly as good recoveries of RNA were found in the other alcohol treatments, although those involving magnesium chloride indicate some loss at *p*H 6·0 and 7·0. Whenever water was added, the results were erratic and showed *Mx*/*Mn* ratios less than 2, indicating the presence of material other than RNA. It appeared that substances contributing to the high absorbance of the neutralized hydrolysates were water-soluble but were eliminated by the addition of alcohol. This is depicted in Fig. 1, where absorbance of the hydrolysates at 7·0 and of the alcohol-treated solutions at *p*H 5·0 are shown.

As indicated in Fig. 1, the addition of water to the neutralized hydrolysate solubilized substances with absorbance at 260 mμ of about 1·75. At this same *p*H

Table 1. EFFECT OF *p*H AND WATER, ALCOHOL OR ALCOHOL AND $MgCl_2$ ON THE RECOVERY OF RNA IN ALKALINE HYDROLYSATES OF LEAF TISSUE

(Absorbance of purified yeast RNA at 260 mμ—reference standard)

Sample	*p*H	Solvent	RNA (mg/g* dry wt.)	*Mx*/*Mn*

2	5·0	Ethanol and $MgCl_2$	7,743	2·09
3	5·0	Water	7,299	1·70
4	6·0	Ethanol	7,637	2·22
5	6·0	Ethanol and $MgCl_2$	7,442	2·22
6	6·0	Water	7,822	1·61
7	7·0	Ethanol	7,694	2·14
8	7·0	Ethanol and $MgCl_2$	7,317	2·02
9	7·0	Water	7,834	1·66

* 1 μg RNA = 0·0225 *A* at 260 mμ.

the treatments involving ethanol and ethanol plus magnesium showed absorbances at 260 mμ of about 1·4 and 1·1 respectively. All except the magnesium chloride had high absorbance at 230, part of whichw as contributed by the column. The differences in the alcohol and alcohol plus magnesium chloride seem to be due to another fraction which is not adsorbed on the column (Fig. 2). The base curve (3) represents the absorbance of the alcohol–*p*H 5·0 treatment and is identical with the absorbance of the alcohol plus magnesium chloride at *p*H 7·0. The area between curves 2 and 3 in Fig. 2 is roughly equal to the area between curves 2 and 3 in Fig. 1.

These observations indicate the presence of interfering substances that are soluble in water but precipitated by 50 per cent alcohol in hydrolysates of leaf material to be analysed for RNA. These substances, if not removed by alcohol precipitation, give high absorbance at 260 mμ. Further, the addition of magnesium ion as magnesium chloride and adjustment of the *p*H to 5·0 aid in the precipitation of these and other substances which do not pass through the column, thereby decreasing its efficiency.

PHYSIOLOGY

Effect of Season and Environment on the Retinal Pigments of Two Fishes

DARTNALL *et al.*[1] have shown that in the paired-pigment species *Scardinius erythrophthalmus* (visual pigments based on vitamin A_1 and on vitamin A_2) the retina is dominated by the vitamin A_2-based pigment in the winter and by the vitamin A_1-based pigment in the summer (in England at latitude 52° N.). The present report concerns a similar investigation on two species of fishes living in their natural habitats at lat. 25° N. in Florida, U.S.A. One species, the poeciliid *Balonesox belizanus* Kner, was caught in an area of saline canals (average salinity about 10 parts per thousand), while the other, the cyprinid *Notemigonus crysoleucas boscii* Valenciennes, was caught in two environments separated by some 60 miles from each other. One of these, the 'Cutler Rd. location', was an area of drainage canals completely isolated from any other body of water throughout the period of the investigation (18 months)[2], whereas the other, the 'Loop Rd. location', was part of the canal, lake and swamp system covering most of south Florida and known as the 'Everglades'. Both these environments were fresh water (average salinity below 1 part per thousand).

Methods of extraction and analysis have been fully described elsewhere[2,3]. *Notemigonus* has pigments with λ_{max} at 529 (vitamin A_2-based) and at 502 mμ (vitamin A_1-based)[2]; *Balonesox* has pigments with λ_{max} at 521 (vitamin A_2-based) and at 498 mμ (vitamin A_1-based). The results of analyses of retinal extracts from these fishes taken during October 1962–March 1964 are summarized in Fig. 1. (It is now known that the proportions of vitamin A_1- and vitamin A_2-based pigments may vary considerably from fish to fish[2]; consequently the data of this figure refer to the mean composition of separately analysed extracts from individual fish in each batch.) Common to all three sets of data (those of *Balonesox* and those of *Notemigonus* from the two locations) is the result that the proportion of vitamin A_2-based pigment is at a minimum during the summer and at a maximum during the months of January and February. These positions virtually correspond to those found for *Scardinius* by Dartnall *et al.*[1]. Corresponding extract λ_{max} for the August minimum and for the January–February maximum are listed in Table 1, showing that, according to the time of year, mean extract maxima may change by as much as 13 mμ in the Cutler Rd. *Notemigonus*, 11 mμ in the Loop Rd. ones and 14 mμ in *Balonesox*.

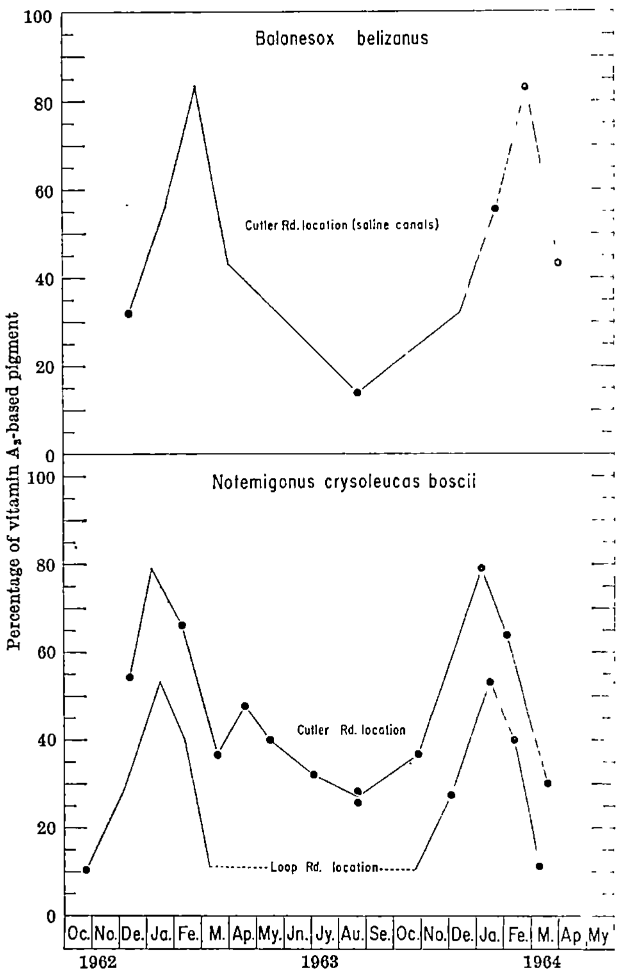

Fig. 1. Seasonal variation in the proportion of vitamin A_2-based pigment in the retinæ of *Balonesox* and of *Notemigonus* batches from two different locations. Where no points are shown at the angles in the diagrams, the figures from other years have been transposed

Whatever the physical causes of this variation (see, for example, refs. 1 and 4), it must be assumed that it has very considerable consequences from the point of view of the fishes' visual sensitivity. These consequences are likely to be even greater at the red end of the spectrum than a consideration of the λ_{max} alone would suggest. At 660 mμ, for example, the vitamin A_2-based pigment of *Notemigonus* has a photosensitivity some 25 times that of its vitamin A_1-based pigment.

The function of individual variation has been dealt with elsewhere[2]: that is, it may serve to 'broaden' the spectral sensitivity of fish schools. The consistent difference found between groups of *Notemigonus* from the two locations may be related to the observation that the highest proportion of red-sensitive (vitamin A_2-based) pigment occurred in the fish inhabiting waters which were

Table 1

August 1963	508* (506–512)†	—	501 (498–503)
January 1964	521 (518–526)	514 (511–521)	508 (504–515)
February 1964	517 (514–522)	511 (507–514)	515 (510–519)
March 1964	509 (505–515)	505 (503–509)	506 (501–512)

* Mean λ_{max} of extracts (corrected 0–2 mμ for D_{min}/D_{max}).

† Range of λ_{max} observed in the extracts of each individual fish in the group.

generally turbid. The other group, from the Loop Rd., were always found in clear waters. Thus we find, in a paired-pigment freshwater species, a possible parallel with the results of Munz[5], who reported that the fishes of turbid coastal waters possessed pigments with λ_{max} displaced towards the red end of the spectrum when compared with those from fishes of more clear marine waters.

With regard to seasonal variation, there is a striking similarity between the visual pigment changes observed in a cyprinid living in temperate English fresh water at lat. 52° N. (ref. 1), a poeciliid living in subtropical Florida saline water at lat. 25° N. and a cyprinid living in subtropical Florida fresh water also at lat. 25° N. Clearly, it is necessary to seek some varying requirement of visual sensitivity which is common to fishes living in these very different environments.

In conclusion, it should be pointed out that no direct measurements of the spectral sensitivities of these fishes have been made. While it may be justifiably supposed that scotopic sensitivity approximates to the summed light-absorbing properties of the two extracted pigments mixed in their appropriate proportions, it is pertinent to enquire whether the photopic sensitivity of winter fishes is near 620 mμ (as in the vitamin A_2-dominated retina of *Tinca*[6]) and whether that of summer fishes is near 550 mμ (as in animals possessing vitamin A_1-dominated retinæ[6]). Information of this kind would contribute considerably to our knowledge of rod and cone photochemistry.

Free α-Amino-N Content of Peripheric and Hepatic Venous Blood of Normal Adults

ALTHOUGH the α-amino-N content of human peripheric venous blood in health and liver disease is well known, the amino-acid content of the hepatic venous blood has been investigated only in the lower animals. Comparative quantitative analyses of peripheric and hepatic venous blood of human beings have not been carried out. Such analyses could clarify the protein synthesis in the liver. The differences between the inflow of amino-acids by the portal vein and hepatic artery, and as an analogue to this, peripheral circulation on one hand and the excretion of amino-acids by the hepatic vein on the other, are a partial measurement for the protein synthesis from amino-acids by the liver.

The quantitative determination of free α-amino-N was carried out according to the colorimetric ninhydrin method of Müting and Kaiser[1,2]. The advantage of this method is that one needs only 0·1 ml. of serum or plasma. The sensitiveness of amino-acids is very high at a concentration of 0·5γ. As a standard we used a 0·1 per cent aqueous solution of glycine (5γ–100γ). The normal range of error of this method is about ±2·0 per cent.

In 60 healthy adults the v. femoralis was punctured. Over a leading wire a 'Teflon'-catheter was inserted forward for about 10 cm. At this position the sample of peripherous venous blood was obtained. Then a catheterization of the v. hepatica was carried out. With sufficient practice the catheterization of the v. hepatica from the v. cava inferior is relatively easy. In most cases the right lobe of the liver was catheterized. Then the blood-sample of v. hepatica was taken. No complications were observed in any of these cases. Most of our patients suffered from congenital or acquired heart diseases. For the pre-operative diagnosis, a catheterization of the heart was necessary. In these patients no signs of cardial decompensation were found. Clinical and biochemical investigations revealed no damage of liver parenchyma.

For those 60 adults not suffering from liver disease, the average free α-amino-N in the peripheral venous blood was 4·15 ± 0·12 mg per cent. This result is similar to most of the values found in the literature by colorimetric or gasometric ninhydrin-method[1]. In contrast, the free α-amino-N of the hepatic venous blood of these patients was 3·45 ± 0·11 mg per cent. There is a difference of 0·61 mg per cent, which has been proved statistically ($P < 0·0001$).

Normally, the liver circulation is about 1,530 ± 300 ml./min (ref. 3) to 2,500 ml./min (ref. 4). Taking the first value of 1,530 ml./min and a hæmatocrit of 40 per cent, the daily protein synthesis from amino-acids in the liver $= 0·61 \text{ mg} \times \frac{1,530}{100} \text{ ml.} \times 60 \text{ min} \times 24 \text{ h}$ in blood or in serum $\times \frac{60}{100} = 8·04$ g nitrogen. Supposing a liver circulation of 2,500 ml./min, the daily protein production from amino-acids in the liver is about 14 g nitrogen. This value corresponds with the daily excretion of urea-nitrogen in urine (7–15 g in normal adults). Therefore, it will be supposed, the difference from 0·61 mg per cent α-amino-N is caused only by the protein synthesis from amino-acids.

Electrical and Mechanical Activity of Isolated Vascular Smooth Muscle of the Rat

SPONTANEOUS electrical and mechanical activity of smooth muscle from the portal vein of the rat were recorded simultaneously for the purpose of determining the relationship of membrane potential to tension development.

A helical strip, 0·5 mm wide and 3 mm long, was cut from the portal vein of a rat, exsanguinated after being stunned by a blow on the head. Smooth muscle of these strips was found by one of us (S. F.) to show conspicuous spontaneous contractions when suspended in a physiological salt solution (NaCl, 118·9; KCl, 4·7; KH_2PO_4, 1·2; $MgSO_4$, 1·2; $NaHCO_3$, 14·9; dextrose, 5·6; $CaCl_2$, 1·5; sucrose, 49·9; and calcium versenate, 0·026 in mM/l.) at 35°–37° C. The muscle strip was mounted in a narrow 2-c.c. bath connected at either end, via polyethylene tubing, to a 20-c.c. syringe. The two syringes were synchronously driven so that one would withdraw bath solution at the same rate (2 c.c./min) that it was injected by the other, thus keeping the surface of the bath at a constant level. High-resistance micro-electrodes (50–70 M) filled with 3 M potassium chloride solution were used to record trans-membrane potentials; an electro-mechanotransducer (Grass, model *FT* 0·03) recorded muscle contractions.

The insertion of micro-electrodes into the smooth muscle fibres was carried out with a Peterfi-type micro-

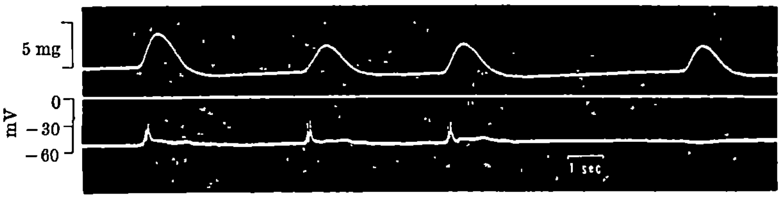

Fig. 1. Simultaneous records of spontaneous electrical and mechanical activity. Upper, middle and lower records are of changes in muscle tension, zero potential and electrical activity, respectively. Note double spike potentials. The particular muscle cell impaled failed to fire at the last contraction

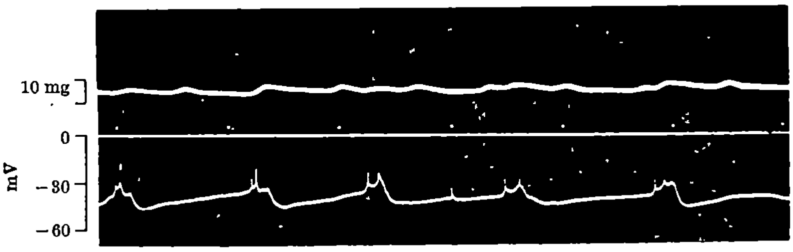

Fig. 2. This record illustrates the irregularity of spike potentials based on slow waves fluctuating at higher amplitude during higher muscle activity. Note the prolonged after-hyperpolarization of the slow waves and the single spike arising from the trough between two waves. Time marks, 5 sec

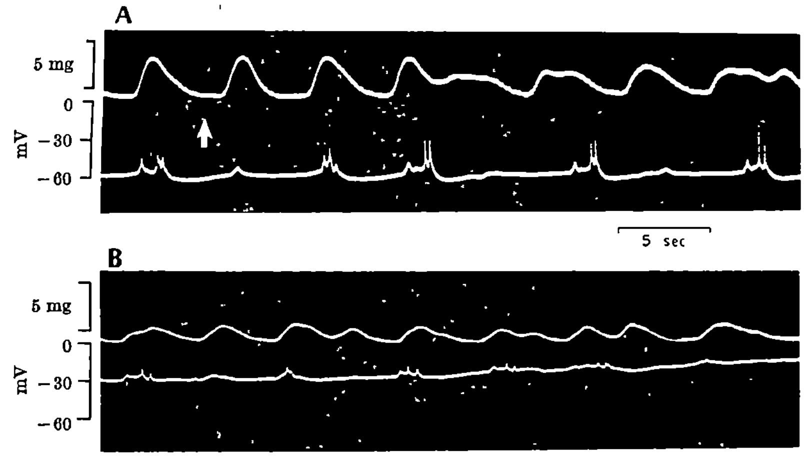

Fig. 3. Effect of adrenaline on electrical and mechanical activity. Arrow in *A* indicates administration of adrenaline (20 μg/l.). *B* is 4·5 min after the administration of adrenaline. Note progressive depolarization of the membrane and change in muscle tension

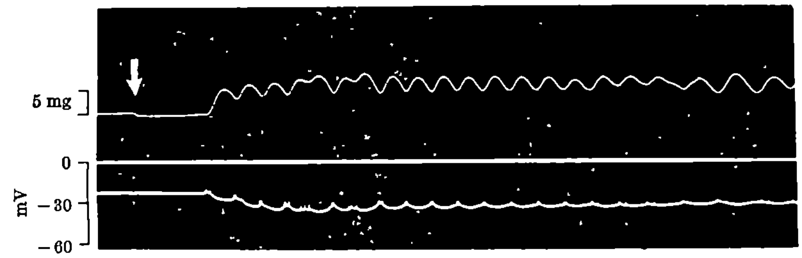

Fig. 4. Effect of acetylcholine on an inactive muscle and the transmembrane potential. Arrow indicates administration of acetylcholine (50 μg/l.), which caused a remarkable hyperpolarization and a summation of contractions. Note the low resting potential of a muscle cell in the inactive muscle. Time marks, 5 sec

manipulator, under binocular microscope with incident illumination. When the tip of the micro-electrode entered a single muscle cell the transmembrane potential always showed a negativity against the external medium, ranging from 30 to 65 mV. The potential sometimes showed slight rhythmic fluctuations or slow waves at various intervals, rarely with an after-hyperpolarization, which resembled those in visceral smooth muscle[1,2]. Transmembrane potentials were measured at maximum polarization during both spontaneous activity and the intervening pause, because, as in visceral smooth muscle, the membrane potential is constantly changing and this is the most readily identifiable value. During rhythmic contractions the changes in muscle tension were preceded by single or double spike potentials arising from the shoulders or summits of slow potentials (Fig. 1). The mechanical activity often formed regular sine waves, especially when contractions occurred at a high frequency (Fig. 4). Individual contractions of the muscle developed about 5 mg tension and lasted only 1–3 sec. This contractile response is much more rapid than any we have observed in other vascular smooth muscle.

Slow waves having an amplitude of 20 mV or more and a duration of 5–10 sec (Fig. 2) were observed. Spike potentials were common on the crests of these slow waves but occasionally occurred in the troughs. Spike duration was 50–100 msec, much shorter than that observed in vascular smooth muscle of the turtle[3]. When spikes occurred in pairs the interval was at least 90 msec. Spike potentials varied from 8 to 30 mV and never displayed a reversal of the membrane potential (overshoot). This again differs greatly from the large potentials, with overshoot, observed in amphibians[3,4]. Using an *in situ* preparation of rat mesenteric vessels, Trail[5] observed single and paired spike potentials, followed by after-hyperpolarization, similar to those that we have seen in the isolated bath.

During the present work the effects of certain agents on the muscle's activity were examined (Fig. 3). Administration of adrenaline, in concentrations of 1–50 μg/l., always increased muscle activity; this effect was accompanied by progressive depolarization of the membrane and increase in spike frequency, in proportion to the concentration of the stimulant. In the initial stage of the process there was an increase in spike potentials associated with an increase in both frequency and amplitude of individual contractions. As depolarization progressed the spike potentials became smaller and more irregular and there was a gradual reduction in tension development.

Acetylcholine in concentrations of 10 μg–200 mg/l. had a diphasic effect on the smooth muscle activity. It caused an increase in membrane potential for a period of 20 or 30 sec up to 2 min, depending on its concentration, accompanied by an increase in spike height and a slight increase in spike frequency. This period of hyperpolarization was followed by the second phase of gradual depolarization, during which there was an increase in spike frequency and the mechanical activity formed regular sine waves.

Some preparations were studied in which membrane potentials were abnormally low and which displayed no action potentials or mechanical activity. Acetylcholine administration to such a preparation caused a remarkable hyperpolarization and initiated frequent rhythmic action potentials and a summation of contractions (Fig. 4). The increase in membrane potential and the initiation of action potentials are probably due to two different actions of acetylcholine.

These observations indicate that in vascular smooth muscle there is a direct relationship between the spike potential and the individual contraction.

PATHOLOGY

Transformation of Embryonic Human Cells by Rous Sarcoma Virus

IT was established in 1957 and 1958 that Rous sarcoma virus (RSV) is pathogenic for mammals and induces hæmorrhagic cysts and sarcomas in rats and fibromas in rabbits[1–4]. These results have been confirmed and expanded by numerous authors, and the pathogenicity of RSV for many other species of mammals has been demonstrated in various laboratories.

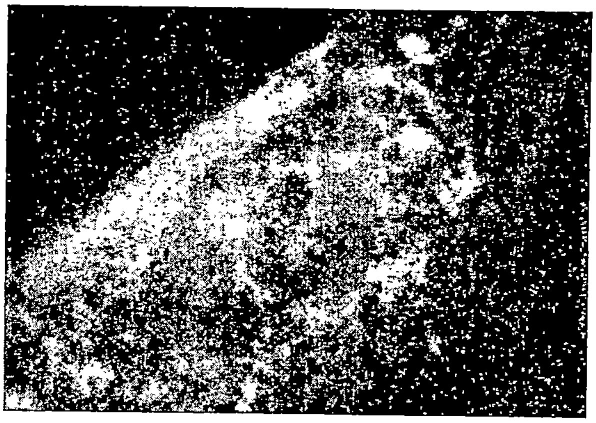

Fig. 1. Cell of infected culture treated with labelled antibodies to Rous virus: specific luminescence of cytoplasm; vacuolization of cytoplasm; enlargement of nucleus (× 720)

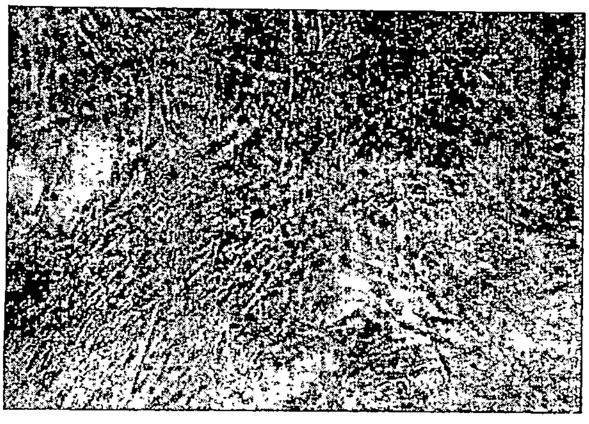

Fig. 2. Foci of multi-layered growth in infected culture after 65 days following infection (× 80)

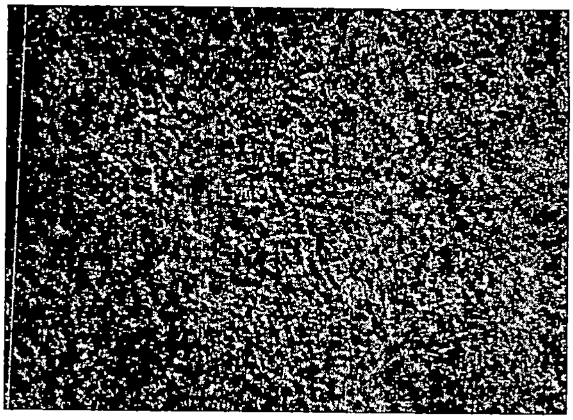

Fig. 3. Infected culture on the seventh day; multilayered growth of cells (× 80)

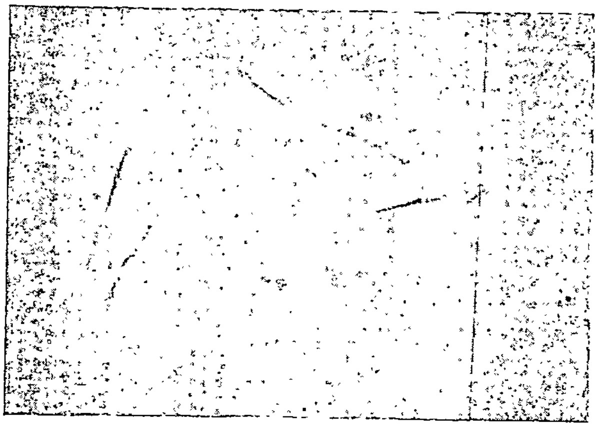

Fig. 4. Control culture during the same period as Fig. 3 (× 80)

The neoplastic transformation of cells by RSV (strain Prague) was also successfully reproduced in tissue culture of rat fibroblasts. The transformed culture was inoculated into rats in which tumours developed. These tumours can be transplanted into chicks by the cells but not by the filtrates[5]. Similar results were obtained with the Bryan strain[6].

In other investigations, the formation of foci of round granulated cells in cultures of rats, mice, guinea pigs fibroblasts infected with Schmidt–Ruppin strain was demonstrated[7,8].

We have examined the possibility of transformation of embryonic human tissue by RSV. For this purpose, we used the Schmidt–Ruppin strain which Prof. Åhlström kindly sent us since it proved to be more oncogenic in comparison with others.

Our technique was as follows. Extracts of Rous sarcoma tissue were added to the fresh suspension of embryonic cells of a human embryo in relation 1 : 2. This mixture was placed for a night on a magnetic stirrer at temperature + 4° C. The activity of this viral extract was tested by titration in 2–3 day chicks, and it was equal to $ID_{50} = 5 \times 10^{-3.5}$ in 1 ml. The same suspension, but without the virus, was placed under the same conditions also for a night.

The next day the examined suspension was washed out with nutrient medium under double centrifugation, and explanted in flasks with the medium of the following composition: 40 per cent Medium 199, 15 per cent bull serum, 15 per cent human serum and 30 per cent bovine amniotic liquid. The control suspension was washed out in the same manner. Renewal was carried out twice a week. Cultures were cultivated at 37° C.

One-and-a-half months later, the cultivation was continued on Medium 199 with the addition of 20 per cent bull serum and 0·1 per cent yeast extract. The passages of cells were made at intervals of 2–3 weeks.

The character of cell growth in the examined and control cultures was identical for 2 months, and the cells in these cultures did not differ from one another under the microscope. Infectious virus was not detected in nutrient medium on the twelfth, twenty-eighth and thirty-third days of cultivation by infection of chicks.

On the thirty-fifth day of cultivation we discovered in infected cells the viral antigen with the help of antibodies to RSV-labelled isothiocyanate fluorescein using Coons's method.

We observed very clear fluorescence of cytoplasm of infected cultures and also considerable vacuolization of cytoplasms and enlargement of nucleus in cultures infected by RSV (Fig. 1). We did not observe such a picture in control cultures not infected with RSV.

At the beginning of the third month of cultivation the foci of intensive cell multiplication in the flask were noted in the infected culture.

Fig. 2 demonstrates the foci of multilayered growth appearing during the following days. Gradually, the cell growth became irregular, forming the multilayered cell mass that grew in different directions (Fig. 3). In control cultures we did not observe any signs of transformation; their growth remained monolayered and became very poor (Fig. 4).

The same results were obtained by Koprowski, Jensen and Girardi (personal communication).

The afore-stated character of transformation gives some evidence to suppose the malignization of our cultures, but further experiments are needed to draw a definite conclusion.

Acidophilia of Aortic Elastin in the Child

In a previous note[1] some results were presented to show that if 5–7-μ sections of human aorta were exposed to 0·025 per cent bromphenol blue (B.D.H. indicator) in *p*H 8·2 Sorensen buffer, then left in distilled or ordinary tap water, aortæ from young subjects retained the dye in the elastic laminæ considerably better than those from the old.

As the maximum resistance to leaching appeared in the young child, a further series has been collected, concentrating on this particular age group. In all, 259 aortæ of children under 7 and 261 aortæ of older individuals, a total of 520, have now been examined. In each case, a portion of descending thoracic aorta was fixed in 10 per cent formol-saline buffered with chalk, embedded in paraffin and cut at 5–7μ.

The method of reading the results has been simplified, and is now more accurate and reproducible. We stain for 20 min in the dye solution, leave overnight (20 h) in water, and grade the residual laminar colour in water under the low power of the microscope: no colour = 0, detectable colour = +, definite colour = + +, strong colour = + + +. The overnight reading seems to be the most consistent as readings at shorter intervals are more affected by minor variations in technique.

In aortæ from subjects older than 7 years, the bromphenol blue is invariably leached by overnight immersion in water. Up to 7, resistance of the dye to leaching develops (Table 1) and regresses (Table 2).

Table 1. Analysis of 184 Aortæ under 1 Month Somatic Age

Weight of infant in grams	Aortæ arranged in groups according to laminar colour remaining after overnight leaching in water			
	0	+	+ +	+ + +
60–500	5	10	1	—
500–1,000	5	19	3	4
1,000–2,000	4	14	11	16
2,000–5,000	2	9	13	68

Table 2. Analysis of 336 Aortæ from Subjects aged 1 Month to 95 Years

Somatic age of subject in years	Aortæ arranged in groups according to laminar colour remaining after overnight leaching in water			
	0	+	+ +	+ + +
1/12–2	—	—	—	59
2–3	—	—	1	2
3–4	—	5	—	2
4–7	2	4	—	—
7–20	17	—	—	—
20–95	244	—	—	—

The results may be summarized as follows. During gestation and the neonatal period, bromphenol blue retention in aortic laminæ is roughly proportional to the weight of the subject, reaching a maximum level at about the age of one month. That level is retained until the age of 2 years, when it begins to fall. There is little left at 4 years, and the maximum somatic age which has shown any degree of bromphenol blue retention is 6 years 10 months.

We thank the City Morgue, the Royal Children's Hospital, the Royal Melbourne Hospital and the Royal Women's Hospital for help in collecting the aortæ used for this investigation.

Metabolic Activity of Neural Crest Tumours in Tissue Culture

Numerous reports have described the raised urinary excretion of metabolites of norepinephrine, and its precursors, by children with tumours of neural crest origin[1–7]. It has also been observed that many of these patients show increased norepinephrine production but produce little or no physiological evidence of increased secretion of this potent catecholamine. Some possible explanations for this apparent paradox are as follows: (1) There might be an adaptation to increased blood-levels of norepinephrine. (2) The norepinephrine might be inactivated within the tumour before release into the blood. (3) A combination of the foregoing two mechanisms might be acting. (4) The rate of inactivation of norepinephrine in tissues other than the tumour (liver, kidney, etc.) might be increased. In a previous investigation, La Brosse and Karon have presented evidence that neural crest tumours contain catechol-*O*-methyltransferase (COMT) activity[8]. Since the 3-*O*-methylated product of norepinephrine has been shown by Evarts *et al.*[9] to be physiologically inactive in comparison with norepinephrine, the finding that COMT activity existed within the tumour indicated that, at least in some cases, norepinephrine may be inactivated before being released into the blood.

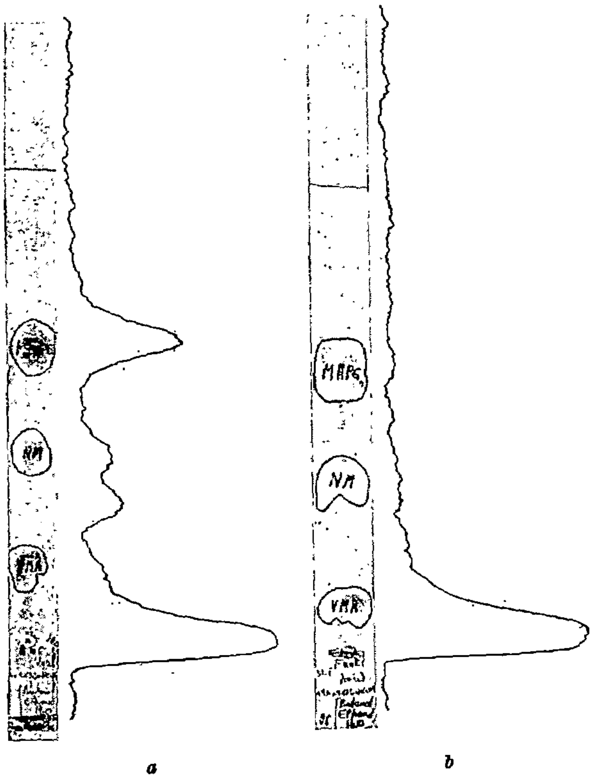

Fig. 1. Radiograms of culture media 48 h after adding 7-^{3}H-noradrenaline hydrochloride. *a*, Radiogram of medium from tube containing a neural crest tumour; *b*, radiogram of medium from tube containing only medium and plasma clot. Abbreviations of reference compounds are: VMA, 3-methoxy-4-hydroxymandelic acid; NM, normetanephrine; MHPG, 3-methoxy-4-hydroxyphenylglycol

In an attempt to obtain further information bearing on these questions, tritium-labelled norepinephrine was incubated with isolated, living neural crest tumours in tissue culture.

Tumour tissue was obtained at operations from 12 patients with neural crest tumours; on histological examination eight tumours were diagnosed as neuroblastomas, three as ganglioneuroblastomas and one as a mixed tumour. The tumour tissue was explanted to plasma clot in tubes containing Eagle's medium[10] and 30 per cent pooled human plasma (or a mixture of 15 per cent pooled human plasma and 15 per cent calf plasma). A mixed cellular outgrowth appeared usually within the first 48 h after explantation. Nerve cells emitting typical neuritic filamentous ramifications were accompanied by fibroblast-like cells and some macrophages. D,L-Norepinephrine-7-^{3}H (^{3}H-NE) (7·5 μc., 1·7 μg) was added to the culture medium (about 1·5 ml.) at 2–6 weeks after explantation; the cultures have always shown the presence of differentiated nervous cells at the time of addition of the labelled compound. For comparison, the labelled norepinephrine was also added to tubes containing plasma clot and culture medium but without tumour. The tubes were incubated at 37° C for 48 h, the culture medium was removed and portions of it were chromatographed on strips of Whatman No. 3*MM* filter paper in the following solvent systems: (1) *n*-butanol/acetic acid/water (4 : 1 : 1), (2) *n*-butanol/ethanol/water (4 : 1 : 1), (3) *n*-butanol/ethanol/water/acetic acid (80 : 20 : 20 : 1), (4) benzene/propionic acid/water (1,000 : 700 : 41), (5) isopropanol/1·4 N ammonia (4 : 1) and (6) butanol/ethanol/ammonia (4 : 1 : 1). Prior to chromatography, reference compounds were added to each strip. After development, the strips were dried and scanned for radioactivity. Finally, they were sprayed with diazotized *p*-nitroaniline. The radiograms of culture medium alone and of culture medium from a tube containing one of the tumours are shown in Figs. 1 *a* an *b*. Comparison of these chromatograms reveals that the are three radioactive areas on the chromatogram of tl medium from the tube containing the tumour whic are not present on the chromatogram of the cultu medium alone. Areas of radioactivity were found correspond to 3-methoxy-4-hydroxyphenylglycol ar normetanephrine in all the solvent systems teste In addition, hydrolysis studies on eluates of the materi which has an R_F of 0·24 in the No. 2 solvent syster already indicated here that this compound is the sulpha conjugate of normetanephrine. In the case of one tumo there was also a tritium-labelled metabolite whi migrated farther than MHPG; the migration characte istics suggest that this compound may be 3-methox 4-hydroxymandelaldehyde.

The formation of the metabolites mentioned he indicates that these explants of tumour contained catech *O*-methyltransferase (COMT), monoamine oxidase (MA aldehyde reductase (AR) and sulphate conjugase (S activities. The presence of COMT activity in tumou of this type has been previously reported[8], and t other enzymatic activities are being investigated.

When D,L-3-methoxy-4-hydroxymandelic acid-7- or D,L-3-methoxy-4-hydroxyphenylglycol-7-^{3}H were add to the culture media as above, there was no evidence further metabolism.

Further work is in progress to establish, beyond reaso able doubt, the identity of the metabolites of ^{3}H- which appeared under the conditions described he additional investigation is also required before it is possi to state whether the metabolic transformations wit the tumour are stereospecific since only the race norepinephrine-7-^{3}H was available to us.

These results indicate that neural crest tumours tissue culture, particularly those from patients who not show signs of excessive norepinephrine secreti but who excrete elevated amounts of norepineph metabolites in the urine, are capable of metaboliz D,L-norepinephrine-7-^{3}H to 3-*O*-methylated compoun This finding provides additional evidence that metab ism as well as synthesis of norepinephrine may oc within neural crest tumours.

IMMUNOLOGY

Rejection of Isogeneic Murine Skin Grafts following Exposure to Allogeneic Ribonucle Acid

TISSUE grafted between non-identical individual ordinary circumstances is recognized as foreign rejected by the host. This rejection is an immunolo phenomenon which is determined by multiple domi histocompatibility genes. The genes are ultimately responsible for the synthesis of lipoprotein histocompatibility antigens[1]. This probably occurs by means of a mechanism which transcribes coded information to messenger ribonucleic acid (RNA), and the subsequent translation of this information determines the specific proteins[2].

The experiments described here were based on the hypothesis that messenger RNA contains the information for the determination of specific histocompatibility antigens; thus the introduction of allogeneic RNA into the cells of a graft could theoretically determine a new protein foreign to the graft. It has previously been reported that cells exposed to foreign RNA can synthesize protein not ordinarily produced by these cells[3,4]. Since multiple genetic differences exist in the usual donor–host homograft relationship, these experiments did not attempt to alter all the incompatibilities. Rather, a system was selected that is sensitive enough to detect any change in one or more histocompatibility antigen(s). This was done by observing the fate of isogeneic mouse skin grafts following their exposure to RNA derived from another inbred strain.

The *C3H/TB* and *BALB/c/TB* inbred strains were used throughout our experiments. They are genetically different at a minimum of 12 histocompatibility loci including Histocompatibility-2. Induction of acquired tolerance between the strains by neonatal inoculation of allogeneic cells has not been possible. Both factors indicate a wide genetic disparity between the lines[5].

RNA was isolated from the livers of the inbred mice by a modification of the phenol method[6]. The interphase of the phenol extract was re-extracted with 0·5 per cent sodium dodecylsulphate containing 0·001 M K_3PO_4 and afterwards extracted with phenol. This was done because the experiments of Georgiev *et al.*[7] and Sibatani *et al.*[8] suggest that messenger RNA is retained in the interphase. All extractions were carried out at 5° C. The final RNA solution was made up in 0·9 per cent sodium chloride. Concentrations of RNA and proteins used in our system are listed in Tables 1 and 2. RNA concentration was determined by the orcinol method[9] and the protein concentration by the method of Lowry *et al.*[10].

Table 1

No. of animals	Host strain	Skin donor strain	Source of liver RNA in incubation media	Conc. RNA (μg/c.c.)	Conc. Prot. (μg/c.c.)	No. rejected	%
4	*C3H*	*C3H*	*C3H*	260	0·3	0	0
10	*BALB/c*	*BALB/c*	*C3H*	260	0·3	9	90
5	*BALB/c*	*BALB/c*	*BALB/c*	700	13·5	0	0

Grafts were incubated in RNA plus balanced salt solution at *p*H 6·5 for 4 h at 37° C prior to grafting.

Table 2

No. of animals each with two grafts	Host strain	Donor skin strain	Composition of media	No. of grafts rejected	%
5	*BALB/c*	*BALB/c* (graft No. 1)	Balanced salt solution	0	0
		BALB/c (graft No. 2)	*C3H* liver RNA in balanced salt solution*	4	80
5	*BALB/c*	*BALB/c* (graft No. 1)	Hydrolysed *C3H* liver RNA in balanced salt solution†	0	0
		BALB/c (graft No. 2)	*C3H* liver RNA in balanced salt solution*	4	80

* RNA concentration = 813 μg/c.c. and protein concentration = 8·1 μg/c.c.

† RNA hydrolysed in 1 N hydrochloric acid at 100° C for 1 h. *p*H re-adjusted with 1 N sodium hydroxide to 6·5.

Donor mice were anæsthetized, skin for incubation was taken from their abdomen, and the adhering fat was removed. The pelts measured approximately 2·5 cm × 3·5 cm and provided skin for 2 grafts after their flotation on the incubation media in sterile glass Petri dishes. The incubation media was either Hanks's or Earle's balanced salt solution. RNA was added after the *p*H of the media had been lowered to 6·5 with concentrated hydrochloric acid. Incubation was carried out for 4 h at 37° C. The grafts were then removed from the solution, placed on filter paper to drain excess fluid, and sutured on to a full thickness bed on the dorsum of host animals. The animals were caged individually, observed for gross signs of graft rejection, and several grafts biopsied on day 7.

Table 1 shows the results obtained in the first experiment. Nine of ten grafts incubated in the allogeneic RNA were destroyed while all control grafts were accepted. The observation that *BALB/c* skin incubated in RNA from *BALB/c* was not rejected by *BALB/c* hosts indicates that a non-specific sensitivity of *BALB/c* skin to RNA was not a factor in the outcome of the experiment. *C3H* grafts incubated in RNA from *C3H* mice were accepted by *C3H* hosts, which indicates that a non-specific toxicity did not influence these results. This does not exclude the possibility of specific toxicity of RNA from *C3H* mice on *BALB/c* skin.

Table 2 shows results from two groups of 5 *BALB/c* mice, each animal with two grafts. The first group of mice had one of its grafts incubated in balanced salt solution without any RNA and the other graft was incubated in *C3H* liver RNA. The second group of animals had one of its grafts incubated in acid hydrolysed *C3H* liver RNA and its second graft was incubated in *C3H* liver RNA. This was done to eliminate the possibility of rejection of grafts on the basis of incompatibility due to factors other than our incubation mixtures. In each of these groups, four of five RNA-incubated grafts were destroyed while all control grafts were accepted.

In both experimental groups, a total of 20 animals showed 17 (85 per cent) that rejected their isogeneic grafts over a period of 10–27 days. Eighteen days was the median and modal time of complete rejection. Gross evaluation prior to the complete destruction and necrosis of the tissue was difficult, but the end result of scarification was obvious. Biopsy of the grafts incubated with allogeneic RNA on day 7 showed an œdematous dermis heavily infiltrated by mononuclear cells and some degree of epidermal atrophy, but no epidermal destruction, at that time. The grafts incubated with isogeneic RNA showed little cellular infiltration. Four *BALB/c* animals that rejected their *C3H*–RNA-incubated isogeneic skin grafts were regrafted with *C3H* skin, and these grafts were grossly rejected by day 7 in two cases and by day 14 in the other two cases. This suggests induction of strong immunity in 2 of the 4 animals. The mean rejection time determined by total graft destruction between the *C3H* and *BALB/c* strains is 12·5 days. Other controls included the subcutaneous injection of RNA from *C3H* mice into 4 *BALB/c* graft sites followed by *BALB/c* skin grafts, and this failed to affect the take of the grafts. Also, the intraperitoneal injection of RNA from *C3H* mice failed to induce accelerated rejection of *C3H* allogeneic skin grafts on *BALB/c* hosts.

These results indicate that it has been possible to alter the antigenic specificity of skin following incubation in allogeneic RNA, when measured in a system of isogeneic grafts. Abolition of the effect by acid hydrolysis of the extract suggests that RNA itself is responsible; however, the presence of specifically active polypeptides is not excluded.

The evidence that the observed effect was due to a change in histocompatibility antigens is suggested by isogeneic graft rejection, accelerated rejection in 2 of 4 animals regrafted with allogeneic skin, and a histological picture at 7 days resembling a homograft reaction. The possibility that the isogeneic rejection is due to the alteration or induction of proteins other than histocompatibility antigens is also recognized. If, however, the change in antigenicity is due to new histocompatibility antigens, it will be important to determine whether or not these replace or add to the existing antigenic complex. This appears to be a fundamental problem when considering the possible clinical applicability of this approach.

Gamma-globulin Synthesis in Hormonally Bursectomized Chickens

IN previous investigations it has been found that the normal development of the bursa of Fabricius in chickens is essential if the bird is to develop fully its potential antibody-forming capacity[1-3]. In these investigations[2,3] the development of the bursa was partially or completely inhibited by the intra-embryonic injection of testosterone propionate. When the inhibition of bursal lymphoid tissue was complete, no antibody production could be detected after challenge at 4–6 weeks of age with 5 different antigens[3]. Providing the thymus in these chickens was morphologically normal, there was no detectable reduction in splenic lymphoid follicles, peripheral blood lymphocyte-levels, or homograft immunity to solid grafts[3]. A marked reduction in cells of the plasmacytic series has been observed in the spleens of both hormonally[3] and surgically[4] bursectomized chickens. As these chickens resembled patients with agammaglobulinæmia[5] in their inability to produce circulating antibodies, physicochemical studies on the serum immunoglobulins were commenced and form the basis of this presentation.

Long and Pierce[6] have previously reported that there was a reduction in the γ-globulin level of a pool of sera from hormonally bursectomized chickens, as determined by electrophoretic and immunoelectrophoretic analysis. Similar work on the sera of thymectomized rats[7] with an impaired antibody response to bovine serum albumin has failed to reveal any abnormality in the β-2M or γ-globulin bands, although a third immunoglobulin line termed *IgX* (perhaps analogous to β-2X-globulin) was absent or reduced in most of the rats.

It is necessary to raise birds to an age of at least 4–5 weeks or older before assessing their globulin patterns, since previous studies[8] have shown that the γ-globulin level declines in normal young chickens, reaching a minimum at about 4 weeks of age, and it is, therefore, impossible to make a statement on newly synthesized γ-globulin prior to this age. Since complete absence of the bursa seems to be incompatible with survival beyond 3–4 months of age, the majority of birds were between 1 and 2 months of age.

All chickens used were outbred White Leghorn 'Australorp' hybrids, and hormonal bursectomy was performed by the intraembryonic injection at 12 days of incubation of 4 mg of testosterone propionate (B.D.H.) in corn oil. The ability to produce circulating antibody was tested by intramuscular challenge with 8 mg of bovine serum albumin after 4 weeks of age. Serum titres were determined 7 days after challenge by the tanned cell hæmagglutination technique. Microimmunoelectrophoresis was performed with a 0·025 M veronal buffer at *p*H 8·2, the precipitation lines being produced with a rabbit anti-whole chicken serum. Analytical ultracentrifugation was performed at 20° C in a Spinco model *E* ultracentrifuge, using a schlieren optical system equipped with phase plate.

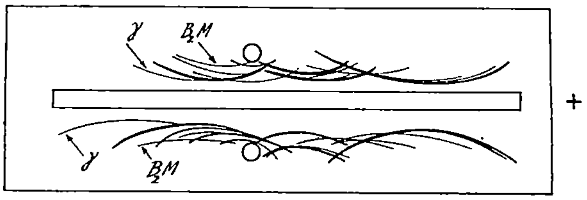

Fig. 1. Immunoelectrophoretic patterns of sera from two birds producing no detectable antibody to bovine serum albumin. The lower pattern shows a normal line while the upper pattern shows a reduced γ-globulin line

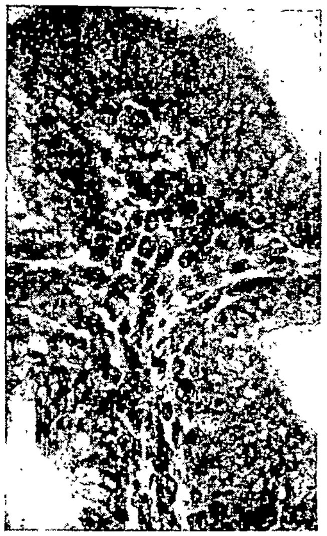

Fig. 2. Bursal remnant of a 5-week-old hormonally bursectomized chicken showing sub-epithelial plasma cell accumulation (Unna Pappenheim stain, × 400)

The sera from 28 1–2-month-old hormonally bursectomized chickens were taken one week after immunization with bovine serum albumin and 17 of the birds were also killed for histological examination. The results in Table 1 show that the γ-globulin line was apparently normal in 14 birds in which antibody production could not be detected, and in 5 birds producing low but significant antibody titres. The β *2M*-line was present in all but 3 of the 28 sera. A typical immunoelectrophoretic analysis is shown in Fig. 1 of two sera from birds producing no detectable antibody to bovine serum albumin, one with a normal line, and one with an apparent reduction of the γ-globulin line.

Ultracentrifugal analysis of 4 normal sera and 7 sera from non-antibody-producing bursaless chickens was performed. The calculated values of 5*S*, 7*S*, and 19*S* fractions (Table 2) revealed a significant reduction of 7*S* material, and a slight reduction of 19*S* proteins. As most of the bursaless birds used in this group were 1–2 weeks younger than the normals, this difference in 7*S* proteins could be actually less for birds of exactly comparable ages. Since each of these two fractions contains several components the reduction could be due to a slight fall in all or a more marked reduction of a single component. In the light of the immunoelectrophoretic result it is probable that the reduction in 7*S* is due to γ-globulin.

Tissues from 17 of the birds were examined histologically for the presence of plasmacytic cells. In 12 birds no antibodies to bovine serum albumin could be detected and in all but one of these birds no lymphoid follicles were seen in

Table 1. COMPARISON OF ANTIBODY TITRE WITH γ-GLOBULIN PRODUCTION IN HORMONALLY BURSECTOMIZED BIRDS

γ-Globulin titre	Antibody titre (normal mean 640)	
	< 10	10–1,280
Normal (8–16)	14	5
Low (4–8)	7	2

Table 2. ULTRACENTRIFUGAL ANALYSIS OF NORMAL AND BURSALESS CHICKEN SERA

	5*S*	7*S*	19*S*
Normal	2·70 (2·41–2·91)	1·44 (0·98–1·77)	0·35 (0·22–0·58)
Bursaless	2·53 (2·04–3·21)	0·53 (0·19–0·83)	0·20 (0·13–0·32)

The values are the mean calculated amounts of protein sedimenting in the respective fractions expressed in g per cent. The range of values is shown in parentheses.

any of several sections examined of each bursal remnant. However, in all cases, variable numbers of plasma cells were found in the bursal remnants, cæcum, and occasionally in spleen. The numbers in the latter two tissues were below normal levels, although in some birds, as shown in Fig. 2, plasma cells were plentiful in the bursal remnant, and were nearly always located directly beneath the epithelial lining. In the remaining 5 birds, low but significant antibody titres to bovine serum albumin were detected after challenge, and in all cases at least a few typical bursal lymphoid follicles were seen in the bursal remnant, and plasma cells were plentiful in the spleen, cæcum and bursal remnant. No correlation was evident between the intensity of the γ-globulin line and the approximate numbers of plasma cells present. Although it is unlikely, other cell types may be responsible, at least in part, for the γ-globulin production observed.

The basic finding presented in this article is that, although antibody production has been depressed to at least below detectable limits, in most hormonally bursectomized chicks, γ-globulin production and plasma cells are quite readily detectable. Studies with sera from normal 1–2-month-old chicks at dilutions of 1/4, 1/8, 1/10 and 1/16 indicate that the γ-globulin line is not usually detectable at dilutions greater than 1/10. Since the sera from most of the non-antibody-producing bursaless chickens contain detectable γ-globulin in dilutions of at least 1/4 (in many cases 1/8), it can be stated that the bursaless chickens synthesize at least 40 per cent of the normal amount of γ-globulin at this particular age. A comparison of antibody titres in normal and 14 bursaless chickens immunized with bovine serum albumin (Table 1) shows that no more than 1 per cent of the normal level of antibody has been produced in the bursaless chickens.

These results imply that in the absence of the bursa of Fabricius, although specific antibody production is not detectable, some form of γ-globulin synthesis is still occurring. Either most of this γ-globulin is 'non-antibody' γ-globulin or else it represents a summation of small amounts of many antibodies which are present individually in amounts too low to detect.

The question of the possible formation of non-antibody γ-globulin has arisen previously in regard to the small amounts of γ-globulin formed by patients with agammaglobulinæmia[5] and in several experimental systems. It has frequently been noted that stimulation of specific antibody production is accompanied by a rise of γ-globulin production which is well in excess of all detectable antibody synthesis[10]. Furthermore, in rabbits subjected to 400 r. whole-body irradiation 24 h prior to immunization with bovine serum albumin, even though no specific antibodies could be detected, an increased production of γ-globulin similar to that found in immunized unirradiated rabbits was observed[11]. In both these situations such an increase has been attributed to non-specific γ-globulin, the nature of which is quite unknown. The possibility has recently been raised that this may represent the non-specific stimulation of many other antibody-producing clones[12].

At the present time we can only speculate as to the precise defect in the chain of specific antibody synthesis in these bursaless birds. The development of the specific receptor site for the specific antigen, the correct mechanism of antigen binding to this site, or correct handling of the antigen by macrophages may in some way be under bursal control, and therefore render these birds incapable of specific antibody production. The rapid restoration of immunological competence to bursectomized birds by a humoral bursal product would be strong supportive evidence for these types of explanations, and is at present under investigation.

We thank Mr. J. Pye for performing the ultracentrifugal analysis described, and Dr. R. Fowler, jun., for his advice. This work was supported by research grants from the Anti-Cancer Council of Victoria, and the National Health and Medical Research Council, Canberra.

RADIOBIOLOGY

Long-life Radioactivity in Occasional Thyroids

IN January and February 1964 radioiodine-131 in cattle and sheep thyroids of the northern hemisphere reached the lowest concentrations (< 0·5 μμc./g) and for the longest time in the past 10 years (see ref. 1 for previous results). The lack of interference by iodine-131 and improved instrumentation have permitted γ-spectroscopy of small amounts of long-life radioactive substances in thyroids and some of these could mistakenly be considered iodine-131. In the first two months of 1964, 1–10 per cent of 520 cattle thyroids were detectably radioactive; the glands were received, unselected, from slaughterhouses in several countries, and the sources reported here were (number radioactive/number not detectably radioactive): Cali, Colombia (10/95); Tokyo, Japan (6/94); South Central United States (2/250).

Specimens were screened for radioactivity by a single-channel pulse height analyser which accumulated the 0·3–0·4-MeV γ-radiation, detected by a 2-in. diameter sodium iodide (Tl) crystal with a sample well 1 in. diameter; this was shielded by 4 in. of lead. The samples, preserved with paraformaldehyde, weighed 15–18 g each and radioactivity was measured for 60–200 min. Occasionally radioactivity was found to be 50–100 per cent greater than the 4·5 c./m background. Repeated measurements of samples containing the most activity showed there was no detectable reduction in the radioactivity after two to four months, therefore the radioactive source was not iodine-131 (half-life = 8 days). Two or three samples from each of the above countries were investigated by a 200-channel pulse height analyser

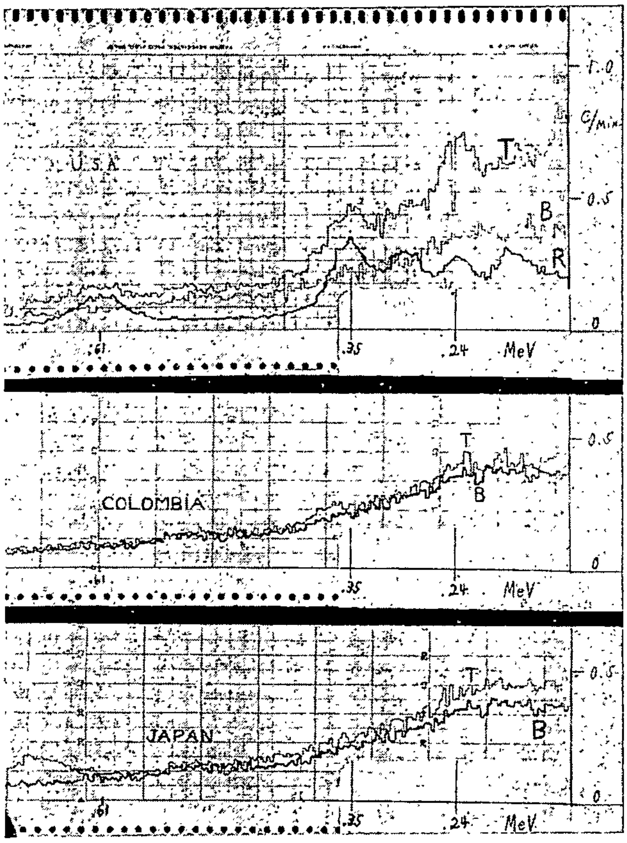

Fig. 1. Output of multichannel γ-spectrometer; 180 channels are shown, covering equivalent γ-energies of 0·13–0·70 MeV. Measurements were made for 10^3 min (16·66 h). The letter *T* is adjacent to the curves obtained from thyroid glands, *B* is adjacent to a 10^3-min background measured immediately before or after the sample, *R* in the top graph shows a spectrum obtained from a radium dial watch shielded by 1 cm water and measured for 10 min; therefore, for *R* curve, the ordinate represents 10^2 greater numbers than for other samples. A technical artefact appears on U.S.A. curve *T* at 0·24 MeV

connected to the 2-in. sodium iodide well scintillation detector. Radioactivity of each sample was accumulated for 16·66 h and Fig. 1 compares three of the results with background and with the radiation from radium (for calibration).

The thyroids from Japanese cattle showed a continuous distribution of γ-energies from the lowest energy to somewhat greater than 0·45 MeV; such a phenomenon is consistent with the Compton continuum to the maximum Compton edge, 0·48 MeV (ref. 2), which should appear in a thin sodium iodide crystal exposed to the 0·66 MeV radiation emitted by the Japanese glands. The glands from Colombia showed a small increase above background in 15 channels between 0·35 and 0·40 MeV; this was analysed by comparing the differences between the means of the 15 paired observations of sample and background counts in the 15 channels; the difference was highly significant ($t = 4{\cdot}1$ and $P \ll 0{\cdot}01$). The energy coincides with the predominant γ-radiation of iodine-131, but the half-life in excess of two months excludes the possibility of iodine-131. The thyroid from the United States had well-defined γ-energies near 0·35 and 0·24 MeV, both of which were suggestive of lead-214, which has a 14-min half-life and is a radioactive daughter of long-life radium-226 (which emits a small amount of 0·19 MeV γ-radiation).

Three thyroids from Colombia had γ-spectra lines like the gland from the United States in Fig. 1, but muscle from the same animals showed only background. Two samples of cattle muscle from Japan contained easily measured 0·66 MeV γ-radiation (probably cæsium-137), but no characteristic γ-peak at 0·3–0·4 MeV was observed.

At least three types of long-life radioactivity in thyroids of grazing animals are reported here: two of them are tentatively identified as cæsium-137 and radium-226; the third is still unidentified. Radium may concentrate in the thyroid and cæsium-137 is widely distributed, but their interference between 0·3 and 0·4 MeV can give a false indication of the 0·364 MeV γ-ray of iodine-131. A serious mistake could result if 0·3–0·4 MeV γ-radiations were measured many months after exposure to iodine-131 and if the observed activity were erroneously 'corrected' for radioactive decay of iodine-131. For example, if the gland from Colombia in Fig. 1 were tested 80 days after slaughter, the small amount of radioactivity above background would be multiplied by 1,024 to 'correct' for ten half-lives of iodine-131 decay. Logically, it follows that several different observations might be necessary to prove the existence of iodine-131 in thyroid glands.

Thyroids were kindly sent to our laboratory every 3–14 days from Dr. Palyo Correa, Cali, Colombia, R. Tanaka, Ibaraki-Ken, Japan, and Mr. John Anthony, Memphis, Tennessee. This investigation was supported by research grant *At*(40-1)-1643 from the U.S. Atomic Energy Commission and *Am-K*6-40 from the U.S. Public Health Service.

Modification of the Radiation Effect on Ascitic Tumour Cells by Pharmacological Agents injected intravenously

THE modification of the effect of radiation on a murine ascitic tumour irradiated *in vivo* by pharmacological agents has been previously reported[1–3]. In those investigations the effect of radiation on the reproductive capacity of ascitic tumour cells was modified by direct injection of the pharmacological agent into the peritoneal cavity, the site of tumour growth. The experiments reported here were performed with intravenous injection of the agent to utilize physiological processes in the host (tumour bearing) animal to transport the pharmacological agent to the site of the tumour. It was our belief that although the concentration of the agent at the site might be limited, the technique would more closely simulate clinical situations where it is frequently not possible to achieve high concentration of a drug at the site of the tumour. The modifications of the effect of radiation on the tumour cells could be measured quantitatively by changes in radiation survival curve parameters.

The tumour used was the ascitic *P*-388 murine lymphocytic leukæmia of the *DBA/2JN* strain. Female mice 3–4 months of age were used exclusively for the routine serial weekly transplants of 10^6 cells injected intraperitoneally in 0·1 ml. volume of Tyrode's solution. The donor mice used in the experiments were also females injected in the same manner; the mice used for the bioassay of the cells after any given treatment were either male or female but of one sex only in each individual experiment.

The irradiations consisted of whole-body exposures of cobalt-60 γ-rays in an enclosed cylindrical irradiation chamber. The techniques have been described previously[4]. The exposure rates during the period of time over which the experiments were performed ranged from 266·3 r./min to 246·5 r./min.

The tumour-bearing donor mice were routinely irradiated 48 h after the intraperitoneal inoculation of the tumour. At this stage of growth the radiation survival curve parameters ($Do = 195 \pm 15{\cdot}2$; $n = 2{\cdot}2 \pm 1{\cdot}1$) (ref. 5) correspond reasonably well with an oxygenated population, therefore oxygen diffusion gradients and transport mechanisms across the peritoneal membrane are assumed to be physiological. Peritoneal invasion by tumour is not demonstrable at this stage of growth.

Three types of pharmacological agents were tested: (1) an alkylating agent (nitrogen mustard); (2) a combination of two sulphydryl compounds (AET + glutathione); (3) a halogenated pyrimidine (BUdR). The injections were made into the tail veins of the tumour-bearing mice with a tuberculin syringe through a 26-gauge needle, and the volumes injected ranged between 0·05 to 0·20 ml. The nitrogen mustard was injected 24 h prior to irradiation of the donor mice in doses of 3·0 mg/kg, 0·1 mg/kg, and 0·03 mg/kg. The AET (*S*, 2-aminoethylisothiuronium · Br · Hbr) + glutathione mixture in a 1 : 3 ratio was injected 10–15 min prior to irradiation in doses of 45 mg/kg of AET and 135 mg/kg of glutathione. This dose frequently caused convulsions and loss of consciousness but was followed within 3 min by apparent full recovery. Higher doses (60 mg/kg of AET and 180 mg/kg of glutathione) caused rapid death following intravenous injection. The powdered AET and glutathione were dissolved in distilled water and neutralized with sodium hydroxide to a *p*H of 7·4 immediately prior to injection which converts the AET to MEG[6]. The BUdR was injected in two doses of 200 mg/kg each at approximately 44 and 24 h before irradiation. The bioassay was performed immediately after the irradiation of the donor mouse using the dilution techniques described previously[7,8], and the recipient mice developing ascitic tumours within 40 days were scored as positive.

Fig. 1 illustrates the radiation survival points obtained after combined treatment with the pharmacological agent and radiation exposure. The survival curve of 2-day-growth tumour following radiation alone[5] is included for comparison. The survival points following treatment with BUdR as well as low. doses of nitrogen mustard (0·1 and 0·03 mg/kg) do not deviate significantly from the control curve. No cytotoxic effect was demonstrated due to drug alone with these low dose-levels of nitrogen mustard or with the BUdR. The radiation survival points following treatment with a greater dose, 3·0 mg/kg of nitrogen mustard, fall at lower levels of survival than the control curve, but do not indicate a significant change in slope from that of the control curve, which suggests additivity of effect. The survival points obtained after irradiation of the cells treated with AET and glutathione are located above the control curve at the higher radiation exposures, indicating a radioprotective effect. The limited amount of the data, particularly at the lower exposures, makes it difficult to ascertain whether the effect is expressed by a change in slope (less steep than the control), by a change in extrapolation number (greater than the control), or a combination of both.

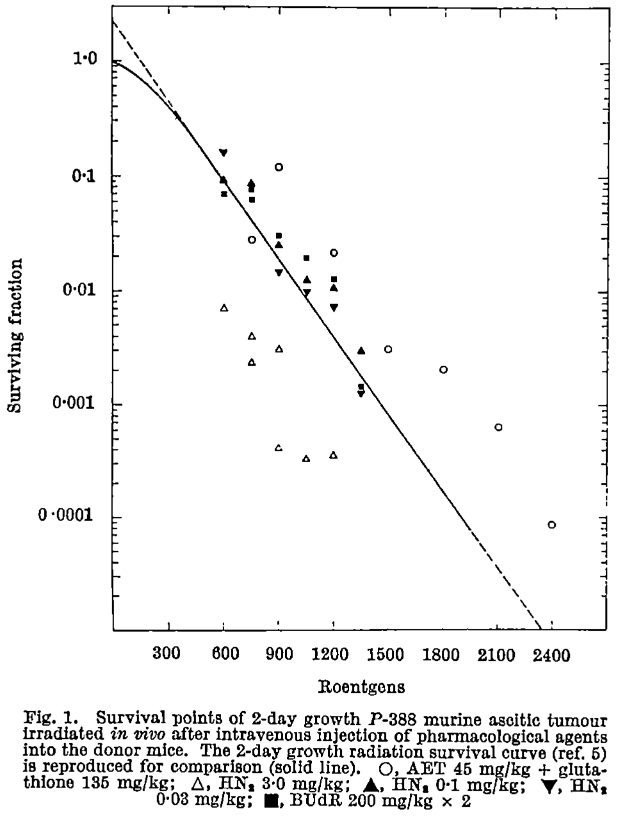

Fig. 1. Survival points of 2-day growth *P*-388 murine ascitic tumour irradiated *in vivo* after intravenous injection of pharmacological agents into the donor mice. The 2-day growth radiation survival curve (ref. 5) is reproduced for comparison (solid line). ○, AET 45 mg/kg + glutathione 135 mg/kg; △, HN$_2$ 3·0 mg/kg; ▲, HN$_2$ 0·1 mg/kg; ▼, HN$_2$ 0·03 mg/kg; ■, BUdR 200 mg/kg × 2

Potentiation of radiation effect has been readily demonstrated with 5-bromodeoxyuridine *in vitro*[9,10]; however, it has been difficult to demonstrate similar effects *in vivo* in spite of direct injection of the compound into the site of tumour growth, the peritoneal cavity, and over a longer period of exposure to the drug than was feasible in our experiments[1,3]. On the other hand, previous pharmacological investigations with halogenated pyrimidines including BUdR have shown that these compounds undergo rapid dehalogenation, principally in the liver, and only a small amount is incorporated into the DNA of normal tissue cells or tumour cells[3,11,12]. We assume this to be the reason for the fact that no potentiation of radiation effect was demonstrated with BUdR administered intravenously in our experiments.

The use of *P*-388 murine lymphocytic leukæmia in the ascitic form has been used to explore a system for quantitatively investigating the effects of combinations of pharmacological agents injected intravenously and irradiation while also demonstrating modification of the radiation effect. The system which we have used has the potentiality for development into such a quantitative combined therapy evaluation system. An additive effect with nitrogen mustard and a protection against radiation effect by AET + glutathione were demonstrated. No potentiation of radiation effect was observed with BUdR.

We thank Miss Marion Matthews, Mr. Bruce Weed, and Mr. Claudius Walker for their assistance in performing these experiments.

BIOLOGY

Graft Transmission of the Flowering Stimulus from a Wild *Beta* Species to a Line of Beet selected for Resistance to Bolting

Successful transference of the flowering stimulus from a bolting beet stock to a scion bred for resistance to bolting has been reported previously[1]. In the work recorded here grafts of similar bolting-resistant scions were made to other species of *Beta* ready to flower. The plants were grown in a glasshouse where long days (16 h) and controlled temperatures (21°C day, 10°C night) were maintained.

In November 1963 early cotyledon stage scions of a line inbred for bolting resistance were inserted into leaf-axils of six-inch flowering scapes of *Beta trigyna*. Six *B. trigyna* stocks, grafted with three scions each, were kept in a humid atmosphere for three weeks, by which time the scions on three stocks had established themselves. In one, the lowermost scion (at the third node) showed stem elongation ten weeks after grafting (Fig. 1) and flowered eight weeks later. The uppermost scions remained dormant and were removed in the tenth week. In the other two stocks all scions prospered to produce large vegetative crowns with swollen stems about two to three centimetres in diameter. Adventitious budding in the stock was suppressed. Control scions inserted in vegetative stocks of *Beta vulgaris* and *B. trigyna* gave no indication of bolting under these growing conditions.

In an experiment in 1959, 65 seedling scions of a bolting resistant *B. vulgaris* line were grafted to members of the *Patellares* group (33 *B. patellaris*, 20 *B. webbiana* and 12 *B. procumbens*). No scions flowered even though the plants were kept from April to December in long-day conditions. Similarly, in 20 reciprocal grafts (10 *B. webbiana*, 7 *B. procumbens* and 3 *B. patellaris* grafted on *B. vulgaris* stocks), although the scions prospered and flowered freely, no flowering was induced in the stocks (Fig. 2).

Any internal flowering stimulus, if such exists, in *B. trigyna* must be the same as, or very similar to, that in *B. vulgaris*, but although the *Patellares* group are annuals in that they flower freely after producing four or five leaves, the stimulus to do so is either unnecessary and presumably lacking, or is incapable of being substituted for that in *B. vulgaris*.

Flowering can be induced in scions which are actively assimilating[1]. It was suggested that the difference in physiological age of the stock and scion might account for the difference between this and previously published observations. In the case of the grafts of *B. vulgaris* on *B. trigyna* there is further evidence that the degree of dominance of stock over scion may be important. In those grafts where the shoot of the stock became dormant, the scions remained vegetative. In another graft of bolting-resistant *B. vulgaris* on flowering *B. vulgaris* the scion flowered only after complete defoliation. Six days after the operation flower buds had formed and were beginning to open, although no stem elongation took place (Fig. 3). The last observation is in agreement with Stout[2], who assumed that the flowering stimulus could only affect scions where the *translocation* stream ran from stock to scion. In view of the flowering of actively growing scions, however, it seems that the dominance need not be related to the direction of translocation stream. On the other hand, it supports the theory of the production of a flowering suppressor in the leaves of the scion.

Infection of Wheat Roots by Ascospores of *Ophiobolus graminis*

In 1933, Samuel and Garrett[1] published their observation that ascospores are violently ejected from the perithecia of the fungus *Ophiobolus graminis* (Sacc.) Sacc. and thus become air-borne; it had previously been supposed that these spores were merely washed down into the soil by rain. Samuel and Garrett, therefore, suggested that the association between outbreaks of the take-all disease of wheat in its whiteheads form and seasons of good spring rainfall in South Australia might be connected with the occurrence of suitable conditions for liberation and dispersal of ascospores, and for subsequent infection of wheat roots by them. Later, however, Garrett[2] reported that he had been unable to secure infection of wheat seedling roots by inoculation with ascospores when the seedlings were growing in unsterilized soil or sand. Infection was readily obtained, however, by inoculation of seedlings growing in completely sterile soil or sand. Garrett explained his results by postulating that the food reserves of an individual ascospore were insufficient for establishment of a progressive root infection, unless supplemented by the microbial nutrients liberated by soil sterilization, or by those provided by root excretions, which would be wholly available to the germinating ascospores in sterile, but not in unsterile, sand.

Garrett, therefore, concluded that infection by ascospores of *O. graminis* was unlikely to play any significant part in the epidemiology of the take-all disease. He pointed out that this disease can be satisfactorily controlled by starving the fungus out of the soil through the practice of crop rotation; this result would not be expected if crops grown on clean land could be regularly and widely infected by air-borne ascospores. In 1946, however, Garrett[3] was shown outbreaks of take-all in wheat crops grown on the recently drained soils of the Noord-Oost polder of the former Zuider Zee in the Netherlands. As described by Bosma[4], the freshly drained soil of a new polder is at first colonized by a sward of grass (and especially by species of *Agrostis*, which are known to be susceptible to infection by *O. graminis*). After ploughing up the grass sward, several crops of wheat are taken in succession; the first may show some patches of the take-all disease, and the second and third crops are often quite severely affected. It is virtually certain that the soil of any new polder, when first drained, is free from the presence of *O. graminis*, so that these observations by Bosma on the Noord-Oost polder once more raised the question as to whether the take-all disease could be spread to clean land by air-borne ascospores.

Although the negative results reported by Garrett in his ascospore inoculation trials seem convincing, several queries can be raised in the light of subsequent work. The dose applied by Garrett was generally 3×10^4 ascospores, applied in 1 ml. suspension; this suspension was either poured on to the surface of the soil around an established seedling, or added to the planting hole before sowing. Although this may seem a large dose, it is now known[5] that some fungal spores have individually a very low probability of infection, so that a massive ED_{50} is required. Secondly, it is known that soil exercises a strong filtering effect on spore suspensions, and it is also possible that placement of spores and timing of spore germination in relation to root emergence and growth may be critical for the occurrence of ascospore infection. With these considerations in mind, it was deemed worth while to make some fresh attempts at obtaining ascospore infection, directing particular attention to placement of spores and timing of spore germination in relation to root emergence.

Perithecia of *O. graminis* for these experiments were obtained both from naturally infected cereal stubble and from the roots of wheat seedlings grown over maizemeal–sand inoculum of the fungus in glass jars exposed to diffuse light. Wheat seedlings (var. 'Cappelle Desprez') were planted on the surface of moist, unsterilized soil or quartz sand in covered glass containers. After 6 days, the first three seminal roots of each seedling had emerged and were beginning to penetrate the soil; at this time the exposed surface of the proximal part of each root was inoculated with one drop (0·024 ml.) of a suspension containing approximately 16×10^4 ascospores/ml. After a further period of 7 days, the exposed and inoculated parts of the seedling root systems were covered with unsterilized soil or sand similar to that on which the seeds had been sown. After 3 weeks from the time of inoculation, all seedlings were washed out for examination of the root system. Most of the inoculated roots showed infection characteristic of the take-all disease; the vascular cylinder was discoloured, and the surface of the root carried dark-coloured runner hyphæ of *O. graminis*. From these inoculated roots, *O. graminis* was isolated in pure culture.

These experiments have shown that, at least under optimal conditions, ascospores of *O. graminis* can infect the roots of wheat seedlings. This finding, taken in conjunction with the observations of Gregory and Stedman[6] on the occurrence of these ascospores in the air spora, suggests the most probable explanation for the appearance of the take-all disease in wheat crops grown on the newly drained polders of the former Zuider Zee.

I thank Dr. S. D. Garrett for suggesting this problem to me. The work was carried out during my tenure of a postgraduate studentship given by the Agricultural Research Council.

Gynodiœcy in New Zealand *Gentiana*

In March 1964 the junior author noticed that populations of *Gentiana bellidifolia* Hook. f., a perennial alpine species, were heterœcious in several places in South Island, New Zealand, mountains. Closer investigation revealed that the populations were gynodiœcious. We sampled a population in Rough Creek basin, Arthurs Pass, at 5,000 ft. by taking one flower from each plant along a transect of some 500 ft. and found the following numbers and proportions of the sexes.

	Hermaphrodite		Female
Number	82		27
Proportion	3	:	1

Some 'intersexes'—flowers with one stamen and four staminodes—were also present. There is no doubt of the functional gynodiœcy of these populations. The proportions of hermaphrodite flowers setting seed were not established because the collection was made too early in the season; but some individuals, both females and hermaphrodites, bore ripening fruit full of seed. Indications are that most hermaphrodites set seed, although a few hermaphrodite flowers with withered gynœcia were seen. No conclusions can yet be made about the mechanism for maintenance of the proportions of the sexes found in the sampled population (see ref. 1 for a brief discussion of the significance of the gynodiœcious breeding system).

The differential expression of sex in flowers of gynodiœcious species is often accompanied by size differences and other heteromorphic differences in floral parts. This pattern is followed by *Gentiana bellidifolia* although there is overlap in flower size between plants of different sex. Fig. 1 illustrates typical flowers of both types and Fig. 2

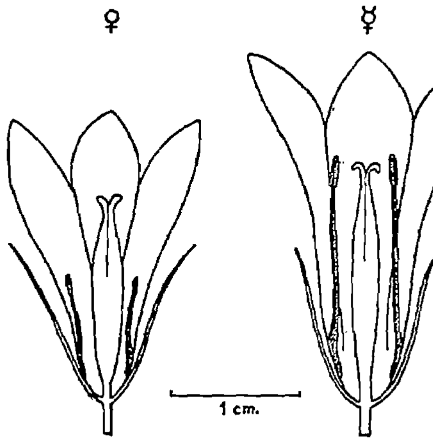

Fig. 1

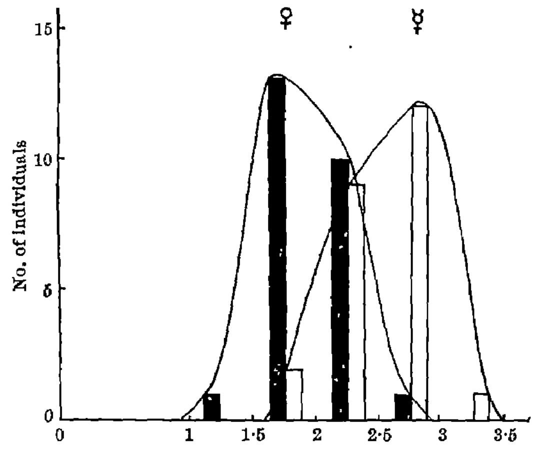

Fig. 2

shows the measurements of corolla length for 25 individuals of each sex.

So far as we are aware, this is the first time that gynodiœcy has been reported for members of the family Gentianaceae. (New Zealand gentians are not close congeners of northern hemisphere species. They belong to a natural group, possibly a distinct genus, found in New Zealand, Tasmania, Australia and South America.) Investigation of possible heterœcy in other members of the family is warranted, since most Floras describe the perfect flower as a family characteristic in the Gentianaceae.

[1] Burrows, C. J., *Trans. Roy. Soc. N.Z.*, 88, 1, 29 (1960).

The observations of Burrows and Hobbs (preceding communication) direct attention again to one of the peculiarities of the New Zealand flora. As far back as 1880, Thomson[1] had observed that "species, genera and families which are characterized by hermaphrodite flowers in other parts are frequently unisexual here". Later work has brought to light a number of examples of gynodiœcy and other sex forms in New Zealand plants that were unknown to Thomson. In December 1961 I noted another in *Ranunculus*, a genus in which gynodiœcism had not hitherto been reported. A large colony of *R. limosella* F. Muell. ex Kirk consisting of many thousands of plants occupying several acres of the dried-up bed of Lake Forsyth on the Banks Peninsula was inspected and a pad of the lake mud was removed to observe the plants in detail. Some of the flowers in this sample were without stamens, and observations over the next few days on freshly opened flowers established that some purely female plants were present with the normal hermaphrodite form. A week later, the site was revisited with Dr. E. J. Godley and a search was made for female plants. None was found until the site of the original sample was rediscovered. At this point there was a small colony of female plants. It is evident that the proportion of female plants in the Lake Forsyth population as a whole was extremely small. A search for female plants in other localities established their presence over a wide area in Canterbury so that gynodiœcism appears to be a normal feature of this species.

According to Parsons[2], the proportion of diœcism in the South Australian flora is significantly greater than in European floras. This he attributed to climatic factors. Comparison with New Zealand, which has a widely different climate and a high incidence of sex forms, does not suggest that climate is of major importance. It is more probable that the important factors are biological and concerned with the pollinating organisms. In Australia brilliantly coloured flowers are abundant and are associated with a high frequency of bird pollination and a numerous fauna of large Lepidoptera. The few brilliantly coloured flowers in New Zealand are bird pollinated, while the majority are small, white or pale yellow in hue and adapted for pollination by flies and beetles; large Lepidoptera are scarce. One factor in common between Australia and New Zealand is the absence of any native large colonial Hymenoptera. Colonial bees in the northern hemisphere are a major factor in effecting cross-pollination, and many floral mechanisms in hermaphrodite plants help to ensure that outbreeding takes place. In the absence of colonial bees, the advantages of outbreeding can be obtained to various degrees by partial or complete separation of stamens and pistils. Conditions in Australia may be expected to favour the evolution of such sexual forms, while in New Zealand the small number of species of bird pollinators and of large Lepidoptera should tend to shift the balance even more in their favour.

Free Sugars in Spores of *Pithomyces chartarum*

Very few analyses of free sugars have been reported in fungal spores. Owens *et al.*[1] found 9·3 per cent hot-water soluble carbohydrate in conidia of *Neurospora sitophila* but only 0·06 per cent free sugars, principally glucose. Other authors[2,3] have found higher amounts of free sugars in fungi. Sussman and Lingappa[4] found 10 per cent trehalose in ascospores of *Neurospora tetrasperma*, while other fungi[5] and yeasts[6] also contain trehalose, often as the main carbohydrate reserve. The conidia of *Neurospora sitophila*, however, apparently contain none[1]. Irani and Ganapathi[2] found free glucose, ribose and a trace of galactose in the mycelium of *Penicillium chrysogenum*. This report gives results of a study of the free sugars in the spores of *Pithomyces chartarum* (Berk. and Curt.) M. B. Ellis.

Spores were collected from rye–corn cultures[7] after drying at 40° for several days. Extraction of sugars from the spores by the usual method with hot 80 per cent (v/v) ethanol was found to be unsatisfactory. Despite thorough desalting, all paper chromatograms streaked badly. Extracts were therefore prepared by disrupting a suspension of spores (1 g in 5 ml. water) in a Hughes press[8]. After centrifuging the resulting homogenate, the cell debris was resuspended in water and recentrifuged, and the combined supernatants were ultrafiltered[9]. A small portion (*A*) of the ultrafiltrate was retained and the remainder (*B*) desalted with 'Biodeminrolit' (Permutit Co.) and concentrated.

The extracts were analysed by paper chromatography, using the solvent systems[10] (1) ethyl acetate–pyridine–water (2 : 1 : 2, top layer), (2) ethyl acetate–acetic acid–formic acid–water (18 : 3 : 1 : 4), and the sprays[10] (1) silver nitrate–sodium hydroxide, (2) aniline hydrogen phosphate, (3) *p*-anisidine hydrochloride, (4) diphenylamine–aniline–orthophosphoric acid, (5) urea–orthophosphoric acid, (6) naphthoresorcinol–hydrochloric acid, (7) diphenylamine–urea–orthophosphoric acid[11]. The monosaccharides were best resolved by two-dimensional paper chromatography in solvents 1 and 2. Sugars on the chromatograms were measured quantitatively by the method of Wilson[12] using aniline hydrogen phosphate spray reagent. Fructose was estimated by comparing the intensity of its silver nitrate sport with those of known amounts of fructose.

Of the silver nitrate-reducing substances present in (*B*), seven were chromatographically identical with glucose, galactose, mannose, fructose, ribose, arabinose and xylose. Concentration ranges (mg/g) were: glucose 5–14, ribose 0·5–2·0, mannose 0·7, fructose 0·3, galactose 0·1–0·15, arabinose and xylose trace only (< 0·1). These sugars were present in approximately the same proportions in two extracts of spores grown on rye-corn and in two extracts of samples of spores grown on glucose and xylose respectively as sole carbon source. The only oligosaccharide present in measurable quantity was identified chromatographically as trehalose, which occurred up to about 0·25 mg/g spores. Its identity was confirmed by its non-reducing reaction with silver nitrate, and the appearance of a substance chromatographically indistinguishable from glucose as its sole hydrolysis product. Other neutral reducing substances present in the extracts did not react with specific sugar spray reagents and were not examined further.

Chromatography of the undesalted extract (*A*) revealed several silver nitrate-reducing substances, but only one was present in significant quantity. This latter substance was acidic, and gave colour reactions typical of sugars. Its constitution is as yet undetermined.

The present report extends the number of free sugars known to occur in fungal spores. In total, the sugars identified constitute approximately 1 per cent of the dry weight. In contrast to findings in some other fungi[4–6] trehalose was found to be only a minor constituent of *P. chartarum* spores. Studies on the polysaccharides are in progress and will be reported elsewhere.

Failure of the ethanol extraction, the classical method of extracting sugars from plant material was entirely unexpected and is as yet unexplained. I thank Dr. R. W. Bailey for his advice.

Effect of Hydrogen Sulphide on *Bullia* (Gastropoda)

THE toxicity of hydrogen sulphide to mammals and certain other vertebrate animals is well known, and it is generally considered that the lethal effects of this substance are due in part to direct combination with the animal's hæmoglobin, leading to the formation of choleglobin and sulphæmoglobin, as well as to the inhibition of several enzyme systems associated with heavy metals. Invertebrate animals do not appear to have been investigated in this respect, excepting only *Arenicola marina*, the hæmoglobin of which does not combine with hydrogen sulphide but is a very active catalyst of sulphide oxidation[1]. By means of this, and possibly other, mechanisms, the worm is able to tolerate high concentrations of sulphide for lengthy periods.

The production of sulphides in marine sediments has been examined by Bruce[2], Galliher[3] and other workers, while a review of the subject is provided by Perkins[4]. Marine ecologists have noted the absence of macro-organisms from regions so affected and have tended to link this with the lack of oxygen in the 'black layers'. The present observations on *Bullia* were initiated by the disappearance of *B. laevissima* and *B. digitalis* from the Harbour Beach and the North Beaches respectively of Hout Bay, beaches on which these sand-burrowing prosobranchs were previously abundant (*vide* Brown[5]). The gradual disappearance of these molluscs coincides with the increasing organic pollution from the outlet of a fish-meal factory to which the Hout Bay beaches have been subjected in recent years. At the present time the northern beaches of the bay are virtually devoid of macro-organisms between tide-marks, the sand is blackened and disturbance of the substratum releases small quantities of hydrogen sulphide gas. Conditions are not, however, as extreme as have been observed in many relatively unpolluted South African estuaries[6,7].

Individuals of *B. laevissima* and *B. digitalis* were kept in jars of sea-water through which hydrogen sulphide was bubbled. From time to time individuals were removed and placed in fresh, aerated sea-water. All those removed after 0·5 h or longer of this treatment appeared dead and did not recover. Animals removed within 15 min all recovered, though movement had ceased. Of the animals removed at intermediate stages some recovered completely, others did not, and some appeared to recover but were found dead the next day. In a subsequent series of observations, jars of sea-water were bubbled with hydrogen sulphide, an animal placed in each, and the jars then closed without trapping any air. The controls were five individuals of each species placed in identical jars and similarly protected from the air, in water through which nitrogen gas had been bubbled. The test animals ceased all movement within 0·5 h, but those removed within 1 h and 10 min recovered completely. Six individuals removed after 2 h were already dead and of eight removed after 1·5 h only one recovered completely. The control animals were still active after 2 h and were only released the following day, after some 18 h. All showed complete recovery despite having been deprived of oxygen. Hydrogen sulphide is thus lethal to *Bullia* quite apart from oxygen lack, though the animals may be more resistant than are mammals. They do not, however, display a resistance comparable with the polychæte *Arenicola* which, according to Patel and Spencer[1], can survive up to 24 h under the foregoing conditions.

Hæmolymph was extracted from the cephalopedal sinuses of three *B. laevissima* and after being allowed to stand for a moment was placed in a Thunberg tube connected to an exhaust pump. On evacuation of the tube the usual colour change associated with deoxygenation of hæmocyanin was noted. The blood was then shaken in an atmosphere of hydrogen sulphide, left to stand, and again connected to the exhaust pump. I thought I could again detect the change from blue to colourless, but could not be certain due to the obscuring effect of precipitated sulphur. The tube was therefore connected to a Barcroft–Verzar respirometer immediately after allowing the air to rush in. The control tube contained an equal amount of gastropod Ringer of *p*H 7·8, which had been treated in the same way. The blood absorbed over six times as much oxygen as the control. On repeating the experiment with fresh hæmolymph the ratio was 7·5. Thus contact with sulphide does not appear to interfere permanently with the oxygen-carrying ability of *Bullia* hæmocyanin. On the other hand, I have not found any evidence to suggest that the animal is protected by the enzymatic oxidation of sulphide. When hydrogen sulphide is allowed to interact with *Bullia* hæmolymph, using the methods described by Patel and Spencer[1], a large amount of oxidation does, in fact, take place, but I find that this is not greater than occurs in controls consisting of gastropod Ringer of *p*H 7·8.

A final observation which may well be of some considerable ecological significance is that *Bullia* can detect quite small quantities of hydrogen sulphide and tends to avoid such pollution. When ten individuals of *B. digitalis* were placed in a tank, half of which had a substratum composed of sand which had had hydrogen sulphide bubbled through it while wet, all buried themselves in the other half of the tank, where the substratum had not been treated. This was repeated four times (with the same snails) with the identical result. If the entire substratum was treated or if hydrogen sulphide had been briefly bubbled through the water itself, the snails refused to burrow and eventually turned on to their backs and spread their feet, a position which, in the field, encourages transport by waves and water-currents[5]. Such behaviour might well account for the absence of *Bullia* on the beaches mentioned. The detection of hydrogen sulphide is not confined to the osphradium or some other specific chemoreceptory organ, for if a piece of cotton-wool is soaked in sea-water through which hydrogen sulphide has been bubbled, and then applied to any part of the head or foot of a snail which has been removed from the water, violent brushing-off movements are initiated and the proboscis is often everted and extended towards the affected region. The same reactions are used as a defence mechanism against would-be predators, but do not occur if cotton-wool soaked in unadulterated sea-water is applied to the foot.

Adhesive Disk of *Echeneis naucrates*

Recently, Raghbir Singh*, director of fisheries, Madras, sent me a specimen of *Echeneis naucrates* for study. Having suggested[1,2] the presence of a pump at the hind end of the sucker, I dissected it under the binocular microscope and discovered two pairs of longitudinal pigmented canals one of which is broader and overlaps the basal plates on their ventral side towards their outer margins. The other is still further towards the outside, closely bordering the outer tips of the lamellar bars. Having no other specimens for study, I recently re-examined the two specimens sent to me by Dr. Mees, of the Western Australian Museum, Perth, and found that they had not been transferred to the preservative fluid after I had examined them last, so that they had become dried up. But on examining them now I noticed that grooves had formed on the disk in the position in which the outer pigmented canals are present internally.

Some time ago I gave a specimen to a local biological model maker to prepare a plaster of Paris impression of the sucker. He found that it adhered to the plaster and therefore tugged at the tail to get it off. While doing so the lamellar plates were partially opened, just as it happens when a live fish which is attached to a glass plate is pulled by the tail. I noticed no other change at the time in the specimen, which had dried up as the result of the heat produced in the plaster of Paris.

On further scrutiny of the Australian specimens the lateral grooves were intercepted at the hind-end by the presence of the pear-shaped pyriboss, but in the third the groove was continuous posteriorly without any interception. On trying to find out the cause of the difference I noticed that the pyriboss had shifted forwards and was fully accommodated in the posterior chamber exactly as I had pictured, ref. 2.

Pigmentary System of *Diadema antillarum* Philippi

The echinoid *Diadema antillarum* Philippi shows both morphological and physiological (reversible) changes in colour[1,2]; the former is far more complex than previously supposed and the intimate mechanism of the latter may be, in part at least, of a type hitherto unsuspected.

Several kinds of pigment are involved, reddish or purplish hydroxynaphthaquinone[3] and pigment ranging in colour from golden yellow to black. The latter is chemically heterogeneous. Some shows the properties claimed to be characteristic of melanin[4–6], some appears to be chromolipoid, part is a newly discovered, iron-containing pigment of nuclear origin and part may be derived from the naphthaquinone[3].

Pigment accumulates, but not in a simple way. In the skin, the proportion of the various kinds alters: naphthaquinone becomes relatively more conspicuous. There is a turnover of melanin, some of which is discharged directly from effete pigment cells, some is excreted by amœbocytes[5] and much disappears in an unknown fashion. Such pigment is replaced, but not necessarily by the same kind; moreover, not all the melanin has the same origin. It appears in the young in finely granular form in the cytoplasm of epidermal chromatophores, but the melanin, which accumulates later, arises in association with characteristic spheroids, in the cytoplasm of amœbocytes containing phenolases[7], tyrosine[8] (the presumed substrate) as well as 3-indolyl compounds[6]. The existence of the last hints at the presence of ommachromes, but none was found.

Amœbocytes distribute the pigments widely. Much is egested, or left behind by their disintegration, as interstitial pigment in the connective tissue of the test, spines and viscera[3], as well as in the hæmal vessels of the axial organ[8].

Most of the skin pigment is contained in an extensive network of intercellular channels, with walls pervaded by a well-developed system of fibrils which appear elastic in living preparations. Such pigment is aggregated in chromatophores, apparently of the conventional type, which assume appearances varying from punctate to stellate, according to the prevailing lighting[1]. In reality the situation is very different. Only in the very young is cutaneous melanin wholly contained in cells (chromatocytes). They are located at the intersections (nodes) of the channels, along which their processes extend. Most of the chromatocytes soon degenerate, though they persist in some adults to varying extents, particularly in the vicinity of the pattern of iridophores[9]. Degeneration sometimes reveals a remarkable pattern of fibrils spanning the nodes formerly occupied by chromatocytes (Fig. 1).

The pigment in the shrivelled cytoplasm of degenerated chromatocytes becomes compacted to form large rounded masses of melanin constituting the primary pigment (Fig. 2), around which secondary pigment (*S*) accumulates progressively, due to the activities of amœbocytes. Such aggregations, cast in the mould of their cellular precursors, may be called 'chromatoglyphs' (γλυφίς). They embody all the varieties of pigment. Hydroxynaphthaquinone is often predominant, though it is discharged on fixation, and escapes when the channels in living skin are pierced by a micromanipulator.

As secondary pigment accumulates, the reversible colour change, so characteristic of the young, becomes obscured, though it may persist in adults in the vicinity of the iridophores[9].

In preparations of living skin, pigment undergoes continual movement so that parts of chromatoglyphs may become separated and later rejoin. Under the influence of light, pigment is dispersed from the nodes of the network until the tongues extending from adjoining nodal centres meet. When the pigment concentrates again in darkness, it may redistribute itself so as to flow into different nodal centres. Chromatophores may be cut across, and the separate pigment masses can continue to disperse and concentrate under appropriate lighting. The mechanism of movement is obscure. Since the chromatocytes lie free in the nodal centres of the channels, they could extend processes along them in amœboid fashion, but such a possibility would not explain the movement of the 'dead' chromatoglyphs, in which no active streaming movements could be seen during their change of shape. It is possible that the walls of the channels may produce the movements by exerting localized pressure on their contents.

Certain features of the observed movements recall those elegantly revealed by Yoshida in *Diadema setosum* (Leske)[10–12], in which the precise nature of the chromatophores is unknown, though they were assumed to be cellular. If, as in *D. antillarum*, there are chromatoglyphs forming part of an extensive network of channels, progress might be made in explaining some of the observations reported, which have proved difficult to interpret in conventional ways[11]. Thus, the effect of minute light spots on pigment-free areas of skin[10] might be due to motor effects in the channel walls. The apparent re-union of separated portions of chromatophores to form a functional unit[11], and the displacement over considerable distances of pigment *en masse*[11], are at least easier to envisage were there chromatoglyphs, rather than chromatocytes, in fixed locations.

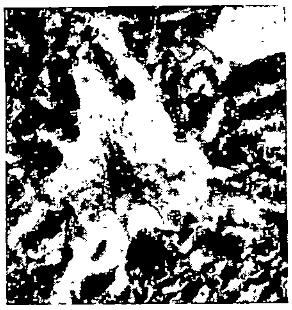

Fig. 1

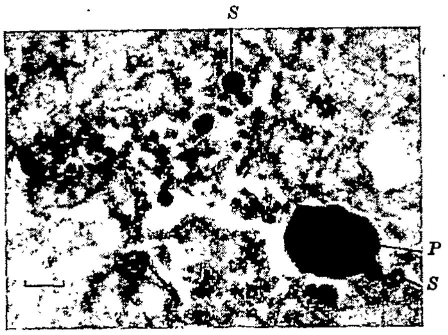

Fig. 2

Fig. 1. *D. antillarum*—a section of the skin in the aboral region of an interambulacrum, cut tangential to the surface, showing an early stage in the formation of a chromatoglyph. The central nucleus and surrounding fibrillar mass is left behind by the degeneration of a chromatocyte. Secondary pigment such as melanin has not yet invaded this region. Heidenhain's Susa fixative, Mallory's triple stain. Magnification as in Fig. 2

Fig. 2. *D. antillarum*—portion of a chromatoglyph as seen in a tangential section of skin, showing the compacted residual cytoplasm of a chromatocyte which forms the primary pigment (*P*) surrounded by secondary pigment (*S*). The pigment is selectively stained by Lillie's ferrous iron method for melanin, the tissue being counterstained in Van Gieson. Scale: 8·0μ

The investigation is being continued, and a full account will be published later. The early part of this work was undertaken in collaboration with Dr. Brenda Manly, whom I thank. I also thank Dr. M. Yoshida for comment and criticism.

ENTOMOLOGY

Phyletic Significance of Some Insect Muscle Pherograms

The analysis of insect hæmolymph proteins has been shown to reflect relationships among species in several insect groups[1]. We have been unable to apply this technique to the bees because the quantities of hæmolymph in adult bees are too meagre to permit analysis. The knowledge that muscle extracts have been shown to be species specific in fishes[2] and are distinct between the lobster and earthworm[3] led us to examine the electrophoretic properties of muscle extracts from several species of bees. Since the thorax of bees is occupied predominantly by muscle, only this tissue was used.

Seven species, representing 5 genera of bees, were collected in the late summer and chilled in an ice chest to immobilize them until they could be quick frozen and stored at –18° C. The cockroach, *Periplaneta americana* L., was used as a standard because of its availability and was obtained from an inbred culture maintained by the department. The frozen bees were removed from the freezer and all of the body parts severed from the thorax. The thorax was opened, rinsed with distilled water and the muscle tissue immediately removed. The tissue was pre-minced with a scalpel and then macerated in a small-volume Potter–Elvehjem type tissue grinder with three times its volume of chilled 0·25 M sucrose for 10 min by hand. The homogenate was then centrifuged at 9,000*g* for 10 min. 15–18 μl. of the supernatant was removed and mixed with large pore sample gel which in turn was applied to the sample tube of a 'Disc Electrophoresis' apparatus (Canalco, Bethesda, Md.), as described by Ornstein and Davis[4]. The 'lower gel' concentration was 7·5 per cent. Electrophoresis of the samples was performed at *p*H 8·9 for 40 min at 2·5 m.amp/tube. The gels were stained for total protein for 3 or more hours in a 1 per cent amido-schwartz 10*B* dye dissolved in 7·5 per cent acetic acid and destained electrophoretically in 7·5 per cent acetic acid.

Representative scans of the protein extract patterns on a Model *E* Microdensitometer (Canalco, Bethesda, Md.) for each species are illustrated in Fig. 1; that for the cockroach is shown at the bottom for comparison.

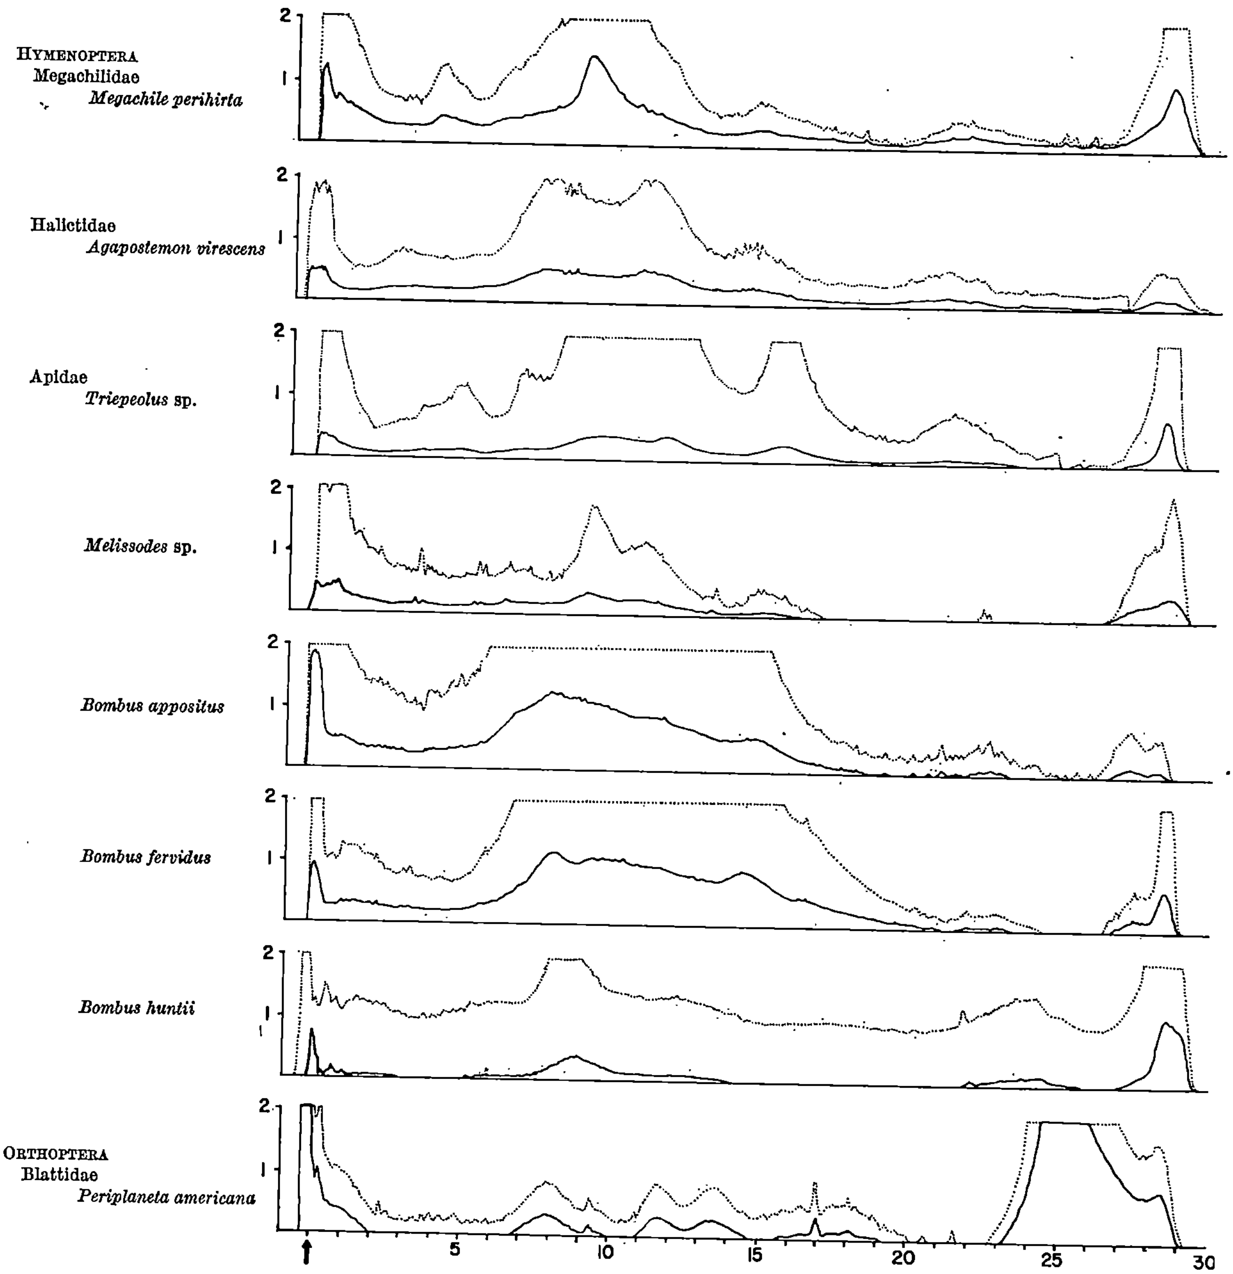

Fig. 1. Microdensitometric pherograms of sucrose extracted muscle proteins. The position at which samples entered the 'lower gel' is indicated by the arrow below the figure. The abscissa scale identifies fractions. The ordinate is optical density. Solid trace is at an optical density of 2 and the dotted trace at 0·2. The anodic area is toward the right

The patterns show a diversity in number and location of soluble muscle proteins from the different species. At this state qualitative differences only are considered.

A comparison of the pherograms of the Hymenoptera as a group with that of the cockroach (Orthoptera: Blattidae) illustrates a definite ordinal distinction. Quantitatively the bees have the major proteins intermediate in mobility while the two major fractions of the cockroach are its most rapidly migrating ones. Further, both groups possess six well-defined peaks of intermediate mobility, but only two or three of these appear to have similar mobilities.

The muscle protein patterns among the three species of *Bombus* resemble each other much more closely than they do any of the other genera, yet they exhibit species specificity. The scans of two of the subgenera, *B.* (*Subterraneobombus*) *appositus* and *B.* (*Fervidobombus*) *fervidus*, are more nearly alike than they are to the third *B.* (*Pyrobombus*) *huntii*. The amount of tissue in *B. huntii* is much less than that of the other two species of bumblebees, which accounts for the reduced concentrations of its fractions. These data suggest that the subgenera *Subterraneobombus* and *Fervidobombus* are more nearly related to each other than they are to *Pyrobombus*, a conclusion that agrees with the phyletic relationships as determined on morphological grounds. The major fractions of the four species of bees, representing the genera *Agapostemon*, *Triepeolus*, *Megachile* and *Melissodes*, closely resemble those of the species of *Bombus* in their mobility. The occurrence of several major fractions in the 6–17 range appears to be characteristic of the bees, contrasting with the trace amounts of these fractions and the excessive amounts of fractions 24–27 in the cockroach (Fig. 1).

There is no difficulty in distinguishing among the five bee genera on the basis of their pherograms, but comparison for the purpose of grouping the genera is premature at this time. The congeneric similarities of the *Bombus* pherograms, their resemblance to those of the other bee genera, and their marked dissimilarity to that of the cockroach suggest that the muscle myogens of insects may prove to be a valuable adjunct to the biochemical systematics of the Hymenoptera. The value of this technique as a tool in interpreting the interspecific, and more particularly the higher category, relationships among the bees and other Hymenoptera is at present being explored in this laboratory.

We thank W. S. Bigley for his assistance and F. W. Plapp, Entomological Research Division, U.S. Department of Agriculture, Corvallis, Oregon, for the use of the Model *E* Microdensitometer.

A High Incidence of Dieldrin-resistance in *Anopheles gambiae* Giles from an Unsprayed Area in Northern Nigeria

IN the course of recent investigations in the northern Guinea savannah of Nigeria on the ecology[1] of *Anopheles gambiae* Giles and *A. funestus* Giles and on their behaviour in huts sprayed with insecticides[2], determinations were made of the susceptibility of both species to DDT and to dieldrin in a area near the town of Kaduna. Apart from very small-scale trials in which a total of 8 village huts were sprayed with DDT and a mixture of DDT and malathion, and apart from the fairly regular use of DDT (but not dieldrin or BHC) as a larvicide on streams in the township of Kaduna, the whole of the northern Guinea savannah can be considered an unsprayed area. The nearest area receiving regular insecticidal house-spraying is the Western Sokoto area, about 200 miles north-west, where DDT has been used since 1957. Prior to this both BHC and dieldrin had been used and dieldrin-resistance in *A. gambiae* shown to be prevalent from 1955[3]. Dieldrin-resistance was also found in *A. gambiae* in 1956[4] in the township of Kano, some 150 miles north-east of Kaduna, and was attributed to the use of BHC mainly for agricultural purposes.

One of us (M. W. S.) performed tests on blood-fed females of *A. gambiae* and *A. funestus* caught from village huts in Kangimi village, some 20 miles north-north-east of Kaduna, in September 1963, using the World Health Organization adult mosquito susceptibility test method. In late October, eggs obtained from gravid female *A. gambiae* from the same village were taken by air to the Ross Institute of Tropical Hygiene, London, where a colony was raised and further adult and larval susceptibility tests carried out by the other of us (G. D.)—adult tests between mid-November and the end of January 1964; larval tests at the end of February and the beginning of March 1964. The results of both field and laboratory testing of adult *A. gambiae* are given in Table 1. Those for *A. funestus* are presented elsewhere[5].

It has previously been shown with many different strains of *A. gambiae* that an exposure of adults to 0·4 per cent dieldrin in 'Risella' oil for 1 h kills all susceptibles but not heterozygous-resistant individuals, while an exposure to 4·0 per cent dieldrin for 1 h kills nearly all heterozygotes but no homozygous-resistant individuals, where the genetic factor involved is partially dominant in its expression[4]; the fact that the mortality at 4·0 per cent is considerably higher than at 0·4 per cent indicates partial dominance in this Kaduna strain. If, then, dieldrin-resistance in this Kaduna strain is the same as the partially dominant resistance previously recorded from other parts of Africa, including Kano and Western Sokoto, the field population consists approximately of 26 per cent susceptibles, 29 per cent heterozygotes and 45 per cent homozygous resistants, and the laboratory colony of 18 per cent susceptibles, 25 per cent heterozygotes and 57 per cent homozygous resistants. The similarity between field and laboratory results is close and the slight differences could be due to the greater survival rate in transit of eggs giving rise to resistant individuals. In addition, differences could be caused by differences in age composition of the two samples of mosquitoes used in the tests, and by differences in the physiological state at the time of testing (in the field only blood-fed females of unknown age were used; in the laboratory unfed females and males 1–3 days old were used).

Table 1. PERCENTAGE MORTALITIES OF WILD-CAUGHT AND LABORATORY-REARED ADULT *A. gambiae* FROM KADUNA, NIGERIA, EXPOSED TO VARIOUS DOSAGES OF DIELDRIN AND DDT IN 'RISELLA' OIL FOR 1 H

Insecticide and dosage (%)	Wild-caught, blood-fed females			Laboratory-reared (London) males and females (unfed), 1–3 days old		
	Total tested	No. dead	Mortality (%)	Total tested	No. dead	Mortality (%)
Dieldrin						
0·4	145	54	26*	62	11	18
0·8	149	69	36*			
1·6	182	100	47*			
4·0	191	118	55*	192	82	43
DDT						
4·0	103	103	100	182	165	91
Control	152	23	15	152	4	3

* Corrected mortalities.

Exposure of blood-fed females in the field to 4·0 per cent DDT in 'Rosella' oil for 1 h resulted in a complete mortality indicating susceptibility to this insecticide. In the laboratory some 10 per cent of unfed females and males escaped the action of this concentration and exposure time of DDT. This is not unusual in the laboratory with susceptible *A. gambiae* using the World Health Organization adult test.

Resistance to dieldrin and susceptibility to DDT were confirmed by the susceptibility testing of fourth-stage larvæ using the World Health Organization larval test method. The LC_{50} for DDT was less than 0·004 parts per million, while survivors occurred on all dosages of dieldrin from 0·0008 to 2·5 parts per million.

Thus, in an area never sprayed with dieldrin or BHC, and where other insecticides have been used only on a very limited scale, 74 per cent of the *A. gambiae* population is already resistant to dieldrin, 45 per cent being homozygous resistant. Such a high incidence indicates that the genetic factor for resistance is not only not a deleterious character but also that under the conditions prevailing in this particular area of northern Nigeria is of some advantage. Other investigations of the natural incidence of dieldrin-resistance in *A. gambiae* have also shown that this resistance is not uncommon in unsprayed areas[6], but nothing as high as the incidence here reported has been recorded before.

Crossings performed in London between the Kaduna colony and known mating-types A and B of the *A. gambiae* complex[7] show it to be an *A* form. Both the dieldrin-resistant strains from Western Sokoto and from Kano are *B* forms. This could indicate that the resistance in the Kaduna area is natural to that area and has not originated from areas further north, or that the resistance has originated from these more northern areas and spread through hybridization between *A* and *B* forms.

Maturation and Egg-laying of the Rabbit Flea (*Spilopsyllus cuniculi* Dale) induced by the External Application of Hydrocortisone

In a previous communication[1] it was shown that maturation of the female rabbit flea could be induced by injecting castrated buck or virgin doe rabbits with a commercial preparation of the anterior lobe of the pituitary gland ('Ambinon *B*', Organon Laboratories, London). In Nature the rabbit flea can only mature its ovaries feeding on a doe during the last 10 days of pregnancy, or on new-born baby rabbits during the first 5 or 6 days of life.

Experiments have now been carried out to investigate which of the anterior lobe hormones controls maturation, and these strongly suggest that the principal factor is the adrenocorticotrophic hormone (ACTH), acting on the adrenal gland to produce corticosteroids above the usual blood-level. Injections into the host of two U.S.P.E. (1 ml.) daily for 14 days of the thyrotrophic hormone ('Actyron', Ferring *AB*, Malmo), and 0·5 mg/day in 3 daily injections of thyroxine ('Eltroxin', Glaxo Laboratories, England) for 14 days, also produce accelerated defæcation and limited ovarian development in the flea (but not full maturation and egg-laying)[2]. This is probably an indirect effect, due to the stimulation by thyroxine of the rabbit's adrenal cortex[3], since female fleas undergo normal maturation and egg-laying when feeding on pregnant and pseudo-pregnant thyroidectomized does. Massive injections daily of 2 mg, for 5–7 days, of œstradiol ('Oestroform', British Drug Houses, London) into the ovariectomized and thyroidectomized host also produce accelerated feeding of both sexes and full maturation and egg-laying of the female fleas in 5–7 days; but this again is possibly the result of a rise in the corticosteroid level in the rabbit's blood due to these abnormally large doses of hormone[4]. In Nature it is unlikely that maturation of the flea is directly influenced by œstrogens, since the ovaries of matured fleas regress rapidly if specimens are fed on does immediately after parturition[4,5], which is nevertheless a period when œstrogens must reach a high level in the rabbit's blood. Maturation is probably initiated and maintained only when the corticosteroids circulating in the blood reach a relatively high level. Thus, daily injections of the non-pregnant adult host (7 lb.), with 1·3 mg of cortisone or more, induced partial to complete maturation of the fleas, but 0·6 mg or less does not.

Negative results were obtained by injecting the host with purified extracts of luteinizing hormone and prolactin, and commercial preparations of progesterone, progesterone and thyroxine combined, oxytocin, testosterone and adrenaline. Full details of these experiments will be published elsewhere.

When it was determined that a daily injection (for 12 consecutive days) of six international units of a commercial preparation of the adrenocorticotrophic hormone ('Acthar', corticotrophin gelatin injection, Armour Pharmaceutical Co., London) or daily injections (for 4 consecutive days) of 1·3–5 mg of cortisone ('Cortisyl', Roussel Laboratories, London) into castrated buck rabbits, virgin doe and thyroidectomized doe rabbits produced uniform maturation of all the female fleas present on the host, an attempt was made to introduce the hormone directly into the parasite.

The fleas were removed from the host and placed in a glass jam-jar. One controlled dose, containing 0·2 mg of hydrocortisone from a new metered 'Hydrocortisyl' skin spray (Roussel Laboratories), was directed into the mouth of the container from a distance of 4 in. The fleas were then replaced on castrated buck and virgin doe rabbits. Maturation of all the female fleas occurred within 2–4 days, generally associated with exaggerated yolk formation; accelerated defæcation of both sexes was noted. The ovaries of these female fleas did not regress for 2–4 weeks, whereas those on hosts injected with 5 mg of cortisone daily, for 8 consecutive days, began to regress after 2–11 days after the injections were stopped. A similar experiment was performed in which the hydrocortisone was replaced by an equal amount of corticosterone. These results were also uniformly positive, although maturation was not so rapid nor yolk production so exaggerated as in the case of fleas sprayed with 'Hydrocortisyl'.

Sprays containing the excipient only, and progesterone instead of hydrocortisone, were used as controls. These sprays did not induce any sign of maturation or increased defæcating rates in the fleas.

The results of the experiments seem to show that hydrocortisone and corticosterone exert a direct influence on the male and female rabbit flea. It is possible, however, that the sprayed fleas could introduce sufficient hydrocortisone on their mouth-parts, while feeding, to produce an effect on the rabbit itself.

It should be stressed that there is a very close relationship between maturation and the feeding behaviour of the flea. In natural infestations on pregnant doe rabbits the defæcation rate of those fleas which are feeding while fixed to the ears (and counts are therefore practicable) is one fæcal pellet expelled every 15 min or longer. Frequently the interval may be more than 30 min. During the last 6–10 days of the rabbit's pregnancy the defæcation rate of both male and female fleas increases rapidly. By the last 2 days before parturition the defæcation rate of a fully matured female flea reaches one pellet or blood droplet (the fæcal matter at this stage is fluid or semi-fluid) expelled every 1–4 min. The same phenomenon can be observed in fleas matured on cortisone-treated hosts (injected with 5 mg) except that in this case the defæcation rate increases more rapidly. This probably reflects an increased feeding and digestion rate rather than merely a more rapid passage of ingested food through the gut. Mead-Briggs[6] has noted hypertrophy of the cells lining the mid-gut in maturing fleas.

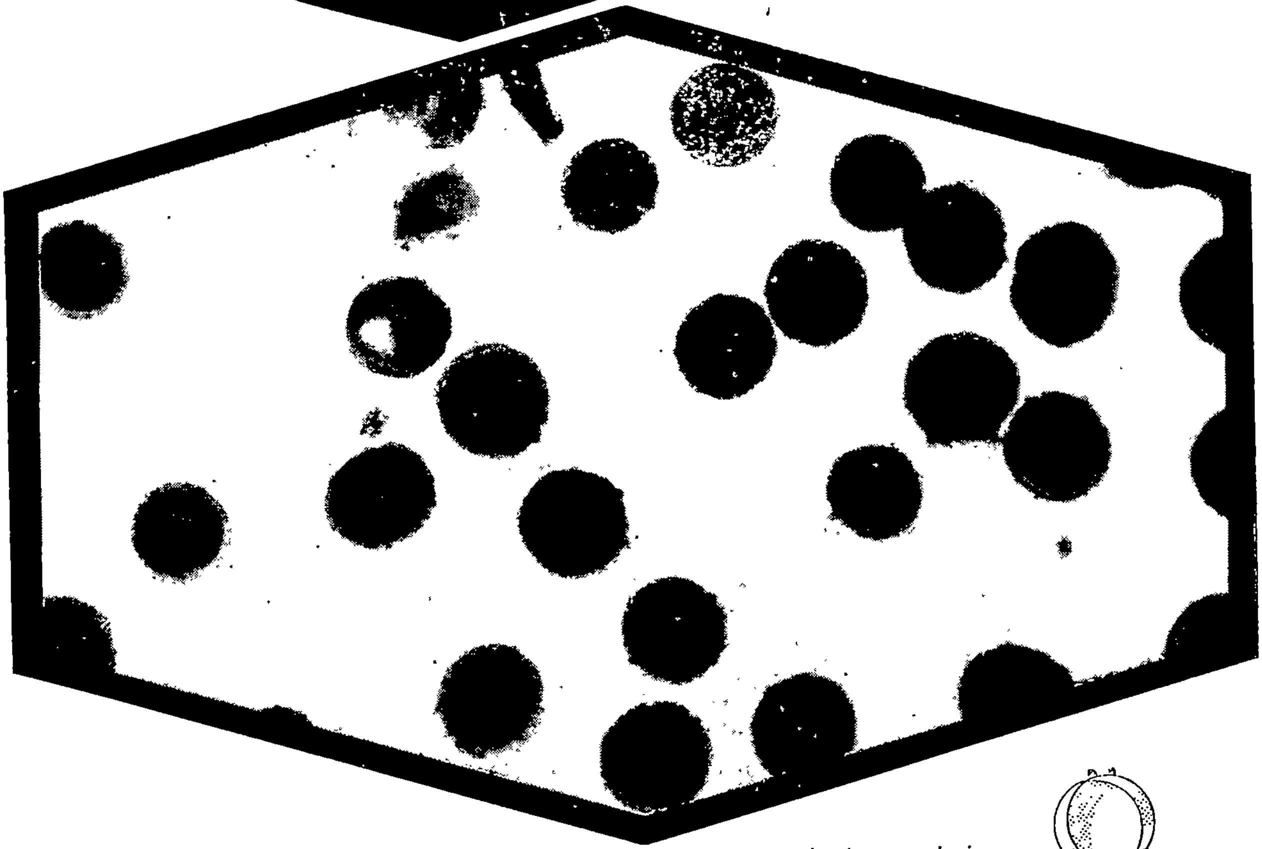
When the host is injected with 5 mg of cortisone and massive doses of œstradiol the fleas quickly respond by becoming restless, and all but a few detach themselves from the ears and are found running about freely in the fur on the head or face of the rabbit. (They do not, however, desert the host for the nest containing young[4,5], as they do after parturition.) These fleas which are loose on the head mature less rapidly and less evenly than those which remain fixed to the ears. Feeding sites near the base of the ears, rather than the edges or the tips, produce the most rapid and even maturation.

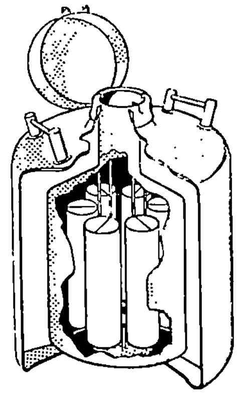
Before the experiments with the Roussel sprays it was assumed that the fleas free on the head were not feeding so steadily and were consequently not ingesting such large amounts of corticosteroids as those which were fixed to the ears. Such an explanation will not suffice in the case of the sprayed fleas, which presumably absorb

We don't store cultures—

but we help to make it possible

UNION CARBIDE





Exhaustive research has proved that liquid nitrogen refrigeration is the best technique for the preservation of cultures and biological specimens. For at cryogenic temperatures there is danger neither of mutation nor contamination, and metabolic reactions are reduced to a negligible level. These advantages have led numerous pathological and biological laboratories to replace their solid CO_2 boxes with liquid nitrogen refrigerators manufactured by Union Carbide.

Union Carbide liquid nitrogen refrigerators provide a constant storage temperature of - 196° C below the nitrogen level and not more than 10° higher above the liquid. Stainless steel construction and special insulation ensure reliability, and the fact that the unit is non-mechanical obviates the danger of specimen loss due to power failure.

Using such agents as glycerol, sucrose and dimethyl sulfoxide to protect living cells from the effects of freezing and thawing, it is possible to store specimens in liquid nitrogen for very long periods with minimum loss of activity and full preservation of cellular morphology. The most popular Union Carbide liquid nitrogen containers are the LR-10A-6, the LR-35-9, and the LR-185. Compared to CO_2 boxes of similar size these containers are very cheap to run.

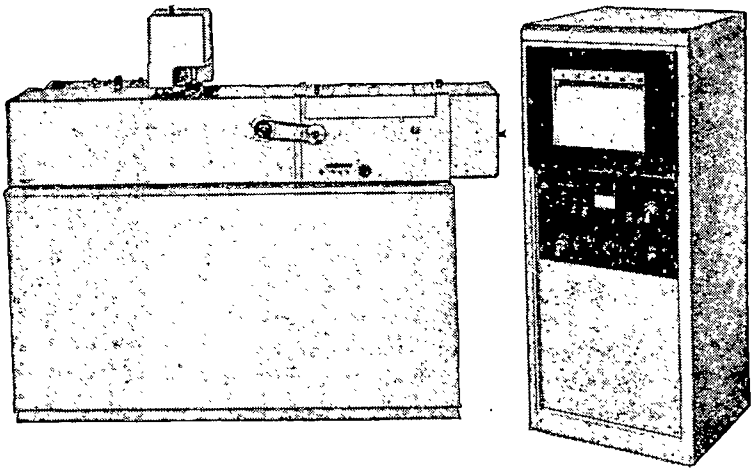
FOR HIGH PERFORMANCE
in routine analysis and research



CF4DR CF4NI

HIGH PERFORMANCE DOUBLE-BEAM RECORDING SPECTROPHOTOMETERS

Noted for photometric accuracy, these OPTICA spectrophotometers include *as standard* a number of features which distinguish them as outstanding among high-performance instruments.

CF4DR Range 185-750 mμ
Price £2,600

CF4N1 Range 185-3,200 mμ
Price £2,800

These instruments are manufactured completely at our Works and are installed free of charge.

Full details of the CF4DR and CF4N1 and other OPTICA spectrophotometers will be forwarded on request.

Standard Features Include:

* Grating Monochromator.
* Linear Transmittance and Absorbance Recording.
* High Resolution.
* Photomultiplier Detector.
* Single Beam Recording.
* Five Scale Expansion Ranges 0-10%T, 0-100%T, 75-125%T, 0-1A, 1-2A.

Complete range of attachments available.

TAS/OA.3

the same amount of corticosteroids through their cuticle in either situation on the host. However, they probably ingest more blood when fixed, which may be significant. The relationship between the hormone, maturation, increased defæcation rate and feeding behaviour of the fleas requires further investigation.

It should be noted that on hosts injected with large doses of cortisone, maturation proceeds more rapidly and is maintained for a longer period than on hosts receiving smaller doses. In view of this fact the observations made on the course of maturation in Nature, when fleas mature in 8–10 days on the doe and in 3 days on baby rabbits[4], suggest that the corticosteroid-levels in the rabbit's blood follow a somewhat similar course to that said to be found in man[7]; a sharp rise possibly occurs during the last 10 days of pregnancy in the female rabbit, which gradually increases or at any rate is maintained until parturition, when it falls abruptly; the level in the blood of the new-born young would appear to be higher than in the doe immediately before parturition.

It was noticed that when the fleas were sprayed *in situ*, on the tip of an unshaved ear of the castrated buck rabbit, with 2 measured doses (0·4 mg of hydrocortisone) from the 'Hydrocortisyl' skin spray, their ovaries matured and had failed to regress after a period of 4 weeks on the host. New batches of fleas were afterwards introduced on to the head of the same rabbit and their ovaries matured although seven weeks had elapsed since the initial spraying of the host. It would thus appear that extremely small amounts of hydrocortisone, which presumably reached the skin via the covering of hairs on the rabbit's ears, remained active for considerably longer periods than the cortisone (5 mg) which was injected intramuscularly for periods of 10–11 days.

Experiments are now in progress with other groups of blood-sucking insects using the Roussel spray technique.

We thank Prof. G. W. Harris for his assistance throughout this work, and Dr. D. Exley, Dr. D. Frazer, Dr. J. Parsons, Dr. R. V. Short and Colonel Robert Traub for helpful suggestions and the gift of various hormones. During discussions covering the possible techniques for external application of cortisone Dr. Parsons suggested the use of the Roussel spray and this was made possible by the co-operation of Dr. V. Wilson and Mr. R. Lawrence of the Roussel Laboratories. We also thank the National Institutes of Health, Bethesda, for the gift of purified hormones, and Mr. R. Allan for cutting the serial sections.

MICROBIOLOGY

Host-range of Temperate *Serratia marcescens* Bacteriophages

It has been reported[1] that phages isolated from sewage against *Serratia marcescens* lyse a single strain each of *Escherichia coli* and *Shigella flexneri*. *S. marcescens* can receive[2,3] lac+ genes from *E. coli* and *Salmonella typhosa* via an episomic vector and may in turn transmit these genes to *S. typhimurium* and *Sh. dysenteriae*.

As part of an investigation to determine whether genes of *S. marcescens* can be transferred interspecifically via phage vectors the host-range of temperate *S. marcescens* phages was investigated. Sixteen N.C.T.C. strains, 1 American Type Culture Collection strain and 14 local strains of *S. marcescens* were examined for lysogeny by methods previously[4] used. Fifteen of the strains (including the American and 7 of the British) proved lysogenic for one or more of the 31 *S. marcescens* cultures. Twelve of the phages were obtained by ultra-violet induction and 3 were present in the supernatants of 10-day broth cultures. The 15 phages could be differentiated by means of their host-ranges.

The action of the 15 phages was tested on a series of *Proteus hauseri*, *P. morganii*, *P. rettgeri* and *Providence* cultures previously used[4] as well as on 12 *S. typhosa* Vi types, 28 other *Salmonella* serotypes, 48 strains of *E. coli* and 24 *Shigella* serotypes. The methods used have been described[4]. Although none of the *S. typhosa* cultures was affected 11 other *Salmonella* serotypes were productively lysed by one or more of all 15 phages. No abortive infections were encountered and the efficiency of plating was unity in all cases. The 11 sensitive *Salmonella* strains belong to the *B*, *C*$_1$, *F* and unclassified groups of the Kauffmann-White schema. No action was noted on strains of the other genera tested.

Many strains of *S. marcescens* are bacteriocinogenic and kill *E. coli* cultures[5,6]. This property of *S. marcescens* has been used[6] as an argument in favour of the classification of *S. marcescens* among the Enterobacteriaceae. The results reported here support this opinion.

This work was aided by grants from the South African Council of Scientific and Industrial Research.

Antibacterial Interaction between Bromthymol Blue and Polymyxin *B*

Polymyxin *B* and bromthymol blue have been used in various selective and differential bacteriological media[1-3]. In the course of recent investigations of various experimental selective media for use in the enumeration and isolation of staphylococci from foods, it was noticed that *Staphylococcus aureus* and *Bacillus subtilis* grew on the surface of plates poured with polymyxin *B* media containing bromcresol purple and phenol red, but did not grow, or grew poorly, on plates of polymyxin *B* media containing bromthymol blue.

A number of experiments have since been carried out to enlarge on these observations because of the possibilities for useful employment of the polymyxin *B*–bromthymol blue interaction in selective media and for other purposes.

A basal-plating medium consisting of: 'Bacto'*-tryptone, 10 g; 'Bacto'-yeast extract, 5 g; *d*-glucose, c.p., 5 g; NaCl, c.p., 5 g; 'Bacto'-agar, 15 g; and distilled water, 1,000 ml., was utilized. Before autoclaving, the reaction of the basal medium was adjusted to *p*H 7·2 and 'Bacto'-bromthymol blue (BTB) was added in the form of a 1 per cent alcoholic solution[3]. The medium was sterilized at 121° C for 15 min and cooled slowly to 45°–50° C. Polymyxin *B* (PB) (obtained from Nutritional Biochemicals Inc., Cleveland, Ohio) was added aseptically as a Seitz-filtered 1 per cent solution. The final reaction of the medium was approxim-

* No growth at the lowest dilution plated.

ately *p*H 7–7·2. The effect of *p*H on the interaction of BTB–PB was studied in three batches of basal medium prepared and adjusted to yield final reactions of *p*H 6·2, 7, and 7·6 after sterilization. Cooled media were poured into Petri dishes and allowed to dry overnight at room temperature before use.

Several PB-resistant test organisms representative of common Gram-positive, Gram-negative, and spore-forming types were employed. *Bacillus cereus*, *B. subtilis*, *Staphylococcus aureus* 196*E*, and *S. faecalis* were obtained from our collection. *Proteus vulgaris*, A.T.C.C. 4669, was obtained from Dr. C. K. Williamson, Miami University, Oxford, Ohio. Stock cultures were maintained by bi-weekly stab inoculations into tubes of low-nutrient, semi-solid medium[4]. Cultures were incubated at 35° C for 24 h and stored at room temperature. For each experiment, fresh transfers were made and used within three days as a source of inoculum. Transfers from these cultures were made into trypticase soy broth (Baltimore Biological Laboratory) and incubated without shaking for 24 h at 35° C. Serial dilutions of these broth cultures were made in phosphate buffered dilution water[5], *p*H 7, and 0·1 ml. of each dilution was spread over the surface of triplicate plates by means of a sterile, glass spreader bar. The seeded plates were incubated for 24 h at 35° C, and resulting colonies were counted on a Quebec colony counter. Each experiment was repeated at least three times.

Tables 1 and 2 summarize typical data on the effect of PB and BTB added singly to the basal medium. Recovery of *B. cereus* was not affected and *S. aureus* only slightly (above 60 μg/ml.) by PB alone. PB decreased the *P. vulgaris* count, but not in proportion to concentrations above 40 μg/ml. These findings compared with those of Pulaski *et al.*[6], who found the sensitivity of *Proteus* species to polymyxin *in vitro* to be greater than 100 μg/ml., and those of Finegold and Sweeney[1], who reported some *Bacillus* species to be resistant to 100 μg/ml. and *S. aureus* to withstand more than 100 μg/ml. The number and size of *B. cereus* colonies on BTB medium were significantly reduced only in concentrations of dye above 0·003 per cent. *P. vulgaris* was not affected by BTB. *S. aureus* colonies were reduced in size and/or numbers in the presence of 0·005 per cent or more BTB; a decrease in viable count of 50 per cent was noted in 0·007 per cent dye. For purposes of studying the BTB–PB combined effect, 0·003 per cent BTB best satisfied the criterion of a dye concentration below which, at *p*H 7, no visible influence was exerted on the most susceptible bacteria, but above which a biological effect was noted. PB at a level of 80 μg/ml. was somewhat arbitrarily chosen for the combined-effect study because it was: (*a*) within the range of slight effect on *P. vulgaris* and *S. aureus*; (*b*) no other clear-cut effect 'end point' was found (Table 1); (*c*) it was the concentration at which the first-chance observations were made.

Because BTB is an acid-base indicator, the effect on plate counts of BTB and PB was tested at *p*H 6·2, 7·0, and 7·6. Table 3 shows marked reductions in viable counts of *B. cereus* and *B. subtilis* on both BTB and BTB–PB-containing media at *p*H 6·2, which indicates that the effect of the combined agents was probably masked by the single effect of BTB at this *p*H level. The combined interaction of BTB and PB against the *Bacillus* sp. was quite apparent at *p*H 7·0 and still detectable at *p*H 7·6. BTB–PB inhibition of *P. vulgaris* was not so great as in the *Bacillus* sp. It occurred at *p*H 6·2 and 7 and was detectable, though less, at *p*H 7·6. The slight suppressive effect of PB alone on *P. vulgaris* noted in Table 1 was again apparent at all three *p*H levels. Viable staphylococcal counts were reduced by about 50 per cent at all three *p*H levels on BTB–PB media and *S. faecalis* counts were reduced at *p*H 6·2, but not at *p*H 7·0 or 7·6.

The results (Table 3) suggest that at *p*H 6·2 enhancement of the activity of BTB was primarily responsible for the observed inhibition by the indicator alone and in combination with PB, although other mechanisms, such as cellular changes that might have predisposed the organisms to the agent, are possible.

Since polymyxin is surface active[6], 'Tween 80' (80 µg/ml.) was substituted for the antibiotic singly and in combination with BTB in experiments similar to those presented in Table 3 to determine if a plain non-ionic surfactant would interact to inhibit bacteria. No significant inhibitory effect was noted at the 3 *p*H levels, except for a slight reduction (usually less than one-half log cycle) in the number of *S. aureus* colonies appearing on media containing both BTB and 'Tween 80' at *p*H 6·2.

Bactericidal action of polymyxin has been reported to be due to a combination with and disorganization of cellular structures that are responsible for maintenance of osmotic equilibrium[7]. Bromthymol blue (3,3′-dibromothymolsulphonphthalein) is an aryl sulphonate chemically similar to many synthetic anionic detergents. The effects of detergents on biological systems include inactivation of viruses, enzymes, toxins, and also bacteriostasis[8]. Like the anionic detergents, the efficacy of BTB in the present investigation was increased by acidity.

One indication of a possible mode of interaction between BTB and PB may be found in the studies of Newton[7] on the mode of action of polymyxin. When washed cells of *Ps. aeruginosa* were suspended by him in dilute solutions of the dye, *N*-tolyl-α-naphthylamine-8-sulphonic acid (which forms a fluorescent conjugate with proteins under ultra-violet light), no fluorescence was observed, indicating the absence of combining groups on the bacterial cell surfaces. Addition of polymyxin to such cell suspensions was followed by immediate fluorescence because of penetration of the dye into the protein-containing portions of the cells. The present experiments suggest that, although PB alone was not fully inhibitory to the resistant species studied, the antibiotic may have been able to exert sufficient disruptive influence on cellular structures to permit penetration of BTB, which exerted the main inhibitory effect. This and the possibility of formation of a PB–BTB antibacterial complex may be worthy of further examination.

Survival of *Shigella* in Sea Water

THE survival of enteric bacteria in sea water has been extensively investigated[1–5]. However, there is a paucity of information on the survival of *Shigella* in sea water. We felt that an examination of the survival of *Shigella* species in sea water was important since it has been a common practice of communities situated on coastlines to utilize the adjacent oceans as a convenient receiver for all domestic wastes. There has been an increase in the use of ocean beaches and tidal areas for recreational activities and commercial shell-fishing; this, coupled with evidence that enteric infections are primarily water-borne, has necessitated certain precautionary measures. This communication records our work on the persistence of *Shigellae* in natural sea water, sea water treated in various ways, artificial sea water and saline solutions. The investigations were performed at various temperatures.

The *Shigella* strains used in these experiments were isolated from Eskimos in Alaska. The cultures were maintained in both nutrient broth and in a chemically defined medium[6]. The organisms were checked periodically by biochemical, morphological and serological methods for purity. Survival of the cells was studied by using a 24-h culture containing approximately 10^8 cells ml. *Shigella* cells were placed in test-tubes containing untreated sea water, filtered sea water, autoclaved sea water, and artificial sea water to determine longevity. In addition, survival was investigated in solutions of 5, 10, 15, 20 and 25 per cent sodium chloride.

Detection of viability was made by placing 0·25 ml. of the sea water into nutrient broth, incubating at 37° C for 24–48 h, and visually measuring growth due to the turbidity. Each experiment was performed in triplicate and the average values are reported. The artificial sea water used in these experiments was a modified formula of ZoBell[1].

The results on the survival of *Shigellae* in sea water are given in Table 1. In general, the organisms did not survive as long in natural, untreated sea water as compared with autoclaved or filtered sea water. There was a wide variation in the ability of different strains to survive in untreated sea water, that is, strain *B*-2501-3 survived more than 70 days whereas strain 12403 survived only 15 days. As a rule the *Shigellae* survived more than 69 days in autoclaved sea water and more than 70 days in filtered sea water. The survival of strain *B*-2547-3 in artificial sea water varied considerably depending on the temperature at which the cells were held (Table 2). Survival was longest at 15° C and 25° C and shortest at 8° C and 37° C.

The *Shigellae* were quite resistant to the osmotic effects of high concentrations of sodium chloride. However, survival depended a great deal on the holding temperature. For example, the cells survived for more than 25 days at −13° C and for only 4 days at 37° C at varying concentrations of sodium chloride. In some instances the *Shigella* were viable even when kept in 45 per cent sodium chloride for 25 days at 8° C.

Untreated, natural sea water has been reported to contain heat-labile toxic substances[7–10]. This could explain the reduction in survival times of *Shigella* in sea water compared with survival in autoclaved sea water. Some workers contend that antimicrobial substances are produced by the micro-organisms in the sea water[11–13]. Our results with investigations using bacteriologically

filtered sea water tend to corroborate this, since the removal of microbial life or some large particulate material by filtration allowed longer survival of *Shigella* in the water. The variations observed in the survival periods in untreated sea water suggest that different strains have different sensitivities to the agent(s) found in natural sea water. Carlucci and co-workers reported that *Escherichia coli* survived longer in heat- and filter-sterilized sea water than in untreated sea water[14].

In artificial sea water the *Shigellae* survived for only 23 days at 37° C compared to more than 106 days at 15° C and 25° C. One possible explanation for this is that the cells were undergoing steady metabolism and therefore death may have resulted from the exhaustion of metabolites. The frozen cells appeared to be preserved for longer periods of time than cells held at 8° C.

Shigella survived for 15 to more than 70 days in untreated sea water. Survival was longer in autoclaved and filtered sea water. The survival of the organisms in artificial sea water varied with the temperature of storage.

PSYCHOLOGY

Units Sensitive to Direction of Movement in Goldfish Optic Tectum

THE retinæ of frog[1], rabbit[2], and pigeon[3] have recently been shown to contain a variety of ganglion cells which signal the direction in which stimuli cross the visual field. The response of such units to a small stationary spot of white light which is briefly flashed at some point within the receptive field has been generally found to be ON–OFF everywhere within the sensitive area[2–4]. Recently, certain units have been found in the retina of the goldfish, *Carassius auratus*, which give a similar pattern of response to stimulation with small stationary spots of white light[5]. However, in the goldfish, no attempt has been made to examine the response of these units to stimuli other than to brief flashes of stationary spots of light. The investigation recorded here examines the response to more complex visual stimuli, and especially the response to moving visual objects.

The fish was clamped between two foam-rubber pads and water containing urethane was circulated through the mouth and past the gills. A small opening was made in the skull to expose the optic tectum, and this was the only part of the fish which remained above water-level. The eye, which was below water, peered out through the transparent side of a 'Perspex' tank at a white screen. Small spots of white light, which subtended an angle of 0·5°, 1°, or 2° at the eye, were projected on to the screen; alternatively, small circular disks of black cardboard (2°, 4°, diam.), mounted on transparent glass rods, were moved in front of the screen by hand. A background illumination of the screen of 1·6 and 1·4 millilamberts was generally maintained during recording sessions to ensure that the retina was light adapted and to reduce the effects of scattered light. Woodsmetal microelectrodes[6] were used for recording action potentials from units in the superficial plexiform layer of the optic tectum. The characteristics of these units were similar to those recorded in the optic nerve and excised retina[5], and this suggests that the responses originated in the terminal arbors of optic nerve fibres.

As the microelectrode penetrates the dorsal surface of the tectum it passes through a region where initially no response is recorded to visual stimulation. The microelectrode then reaches a region where many of the units give responses of the ON–OFF variety to abrupt changes in illumination. Within this layer, many of the units have a concentric field organization which has previously been described for the goldfish by Wolbarsht *et al.*[7]. In units where the ON component of the ON–OFF response increases as one approaches the centre, movement of a small 1° spot of white light from the outside to the centre of the receptive field produces no response. However, the unit responds if the spot is moved radially outwards from the centre. In units where the OFF component of the ON–OFF response increases towards the centre, the unit responds to centripetal movement of the spot. The receptive field of these units subtends an angle of approximately 7°–10°.

Within the ON–OFF layer one also finds units that do not respond to changes in ambient light. Many of these are directionally selective in their response to movement and respond only if the spot of light or black cardboard disk crosses their field in a particular direction and display no response to movement in the reverse direction. Sensitivity to direction of movement is independent of whether the stimulus is lighter or darker than the background, and units respond well to both a small 1° white spot moving against a dark background or a small 2° black cardboard disk moving against a light background. The directional response is also largely unaffected by the level of background illumination (Fig. 1) and is independent of the part of the receptive field through which the stimulus is moved. The response to stimulation with a small stationary spot of white light is generally ON–OFF throughout the receptive field although the relative magnitude of the ON and OFF components at a particular locus may vary somewhat with successive stimulations. The receptive field of this type of unit subtends an angle of approximately 3°–5°. Table 1 presents the number of units which were directionally selective in their response to movement along the vertical and horizontal axes of the fish's visual field. Directional units which responded to horizontal

Table 1

	Direction of movement across visual field	No. of units
Horizontal axis	Temporo-nasal	32
	Naso-temporal	13
		45 Total
Vertical axis	Dorso-ventral	9
	Ventro-dorsal	14
		23 Total

movement were recorded almost twice as often as those which responded to vertical movement, and a χ^2 test shows the difference to be significant at the 1·0 per cent level. In view of the small number of directional units that were examined, any statistical inference drawn from these results must be tentative. However, the results suggest that the goldfish retina may be better equipped to detect horizontal movement within the visual field than it is to detect vertical movement. It is well known that fish possess a visually controlled reflex which allows them to compensate for drift and enables them to maintain a constant visual impression of the bank and bottom of the stream[8]. It therefore is possible that horizontal directional detectors in the goldfish retina participate in the control of this reflex. In addition, the data also suggest that the retina as a whole may be more sensitive to horizontal movement in a temporo-nasal direction within the visual field than it is to movement in the reverse direction (the difference is significant at the 0·5 per cent level). It is known that in a moving stream, a fish generally orients itself so that the head points upstream[8]. When this position is assumed, any tendency for the fish to drift with the current moves the image of the bank and bottom of the stream past the eye in a temporo-nasal direction thereby firing those directional units the sensitivity of which is to movement in this direction. If, indeed, directional units participate in the control of the 'rheotactic' reflex, then the fish's preference to orient itself with the head upstream might account for the fact that the retina is better equipped to detect movement in a temporo-nasal direction.

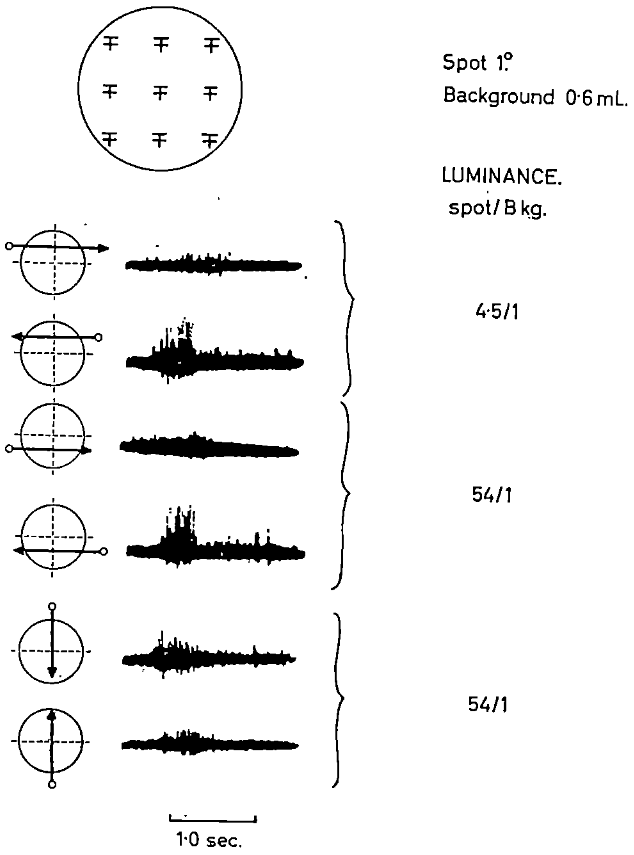

Fig. 1. Effect of intensity on directional response. The unit responds when the spot of light is moved through the field from anterior to posterior, but does not respond to movement of the stimulus in the reverse direction or to movement along the vertical axis of the visual field

As the microelectrode penetrates beyond the ON–OFF layer it enters a region where all recorded units give sustained discharges which signal the level of ambient light. These units are of two kinds, both of which possess characteristically large receptive fields of approximately 15°–18° from which responses of only one kind, either exclusively ON or exclusively OFF, can be elicited when the field is explored with a stationary spot. The sustained OFF units are similar to the dimming detectors described by Lettvin *et al.*[1] for the frog. These units signal a decrease in ambient light and continue to discharge for prolonged periods in the dark. The sustained ON units signal any increase in the level of general illumination and discharge rhythmically for a prolonged period in the presence of an illuminated field. The finding that ON fibres enter the tectum in the goldfish was a little unexpected since in the frog it is reported that ON fibres pass to the diencephalon and that the tectum contains only OFF and ON–OFF fibres[9].

Visual Response to Gradients of Varying Colour and Equal Luminance

Are human visual responses to scenes of constant luminance paralleled by those to scenes of constant chromaticity? This question is of particular interest since MacNichol and Svaetichin have shown[1] that the responses to luminance and chromaticity are separated at the retinal level in the goldfish, and De Valois has shown that they are partly separated in the lateral geniculate body of the monkey[2].

In most phenomena luminance and chromaticity responses are parallel. Consider, for example, the phenomena of brightness constancy and colour constancy. However, Mach bands, which are present in the *Limulus*[3] as well as in man[4] in gradients of varying luminance, are believed to be absent in man in gradients of constant luminance and varying chromaticity. Thouless did not see bands in any of the pairs of colours which he tried, when they were of the same luminance[5]. Koffka and Harrower found bands with one combination of colours only, red on a grey background, and even in this case the bands were vague[6]. Mach himself does not appear to have investigated the question[4].

Mach bands can be seen in many situations, and are particularly evident in two, which will be described as

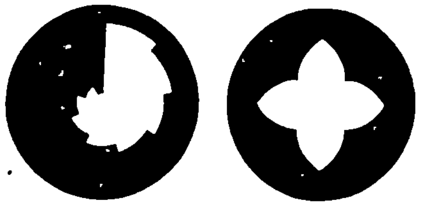

Fig. 1. Disks which, when rotated, show Mach bands. Left disk produces a step tablet, right disk produces a continuous gradient

the 'step tablet' and the 'continuous gradient'. A circular step tablet can be obtained by rotating a Masson disk made from black and white papers (see left half of Fig. 1) at a speed above flicker fusion frequency. This produces a series of steps, each of which is physically uniform, but most of which do not appear to be so. The centre step appears uniformly white, and the outermost step uniformly black, but each of the intermediate steps appears to be dark along the edge lying next to the lighter steps, grading into light along the edge lying next to the darker steps.

A continuous gradient can be obtained by rotating the shape shown in the right half of Fig. 1. In this case it is the centre and outermost areas which are physically uniform but do not appear to be so. The centre area appears to be grey, surrounded by a narrow white circle, and the outermost area to be dark grey, with a narrow black band on its inner edge. The annulus in between shades from white to black.

Gradients of colour are produced by replacing the black and white papers with coloured papers. If, in addition, the disk is illuminated by two projectors with filters over them and a rheostat attached to each of them, the colours of the filters corresponding to the colours of the papers, the observer can vary the relative luminance of the pair of papers continuously. Thouless, and Koffka and Harrower, did not have any means of varying the relative luminance of the papers which they used, in a continuous manner.

Previous investigations were confined to continuous gradients. Most of the following experiments were performed with step tablets, containing ten steps, each 9·5 mm wide. The luminance lay between 1 and 10 millilamberts, and the background was dark. Many combinations of papers and filters were tried: this report concerns six of them, each observed by five people. All observers had normal colour vision.

First the disk was set into rotation, and the observer set the rheostats so that all the steps appeared to him to be of equal brightness. Then he commented on whether or not he saw any Mach bands. These were seen as non-uniformities of the intermediate steps. In the case of a red to green step tablet, for example, the edge next to the greener steps appeared redder than the edge next to the redder step. The centres of the steps progressed from red in the innermost step to green in the outermost, through some unsaturated and neutral colours, rather than through yellow and orange. Next, the observer turned the rheostats slowly to change the relative luminance of the papers, and observed if there was any setting at which the steps appeared uniform, or disappeared altogether. He was asked to turn the rheostats until one paper was lighter than the other, then to turn them back until the second was lighter than the first. During this time his eyes were allowed to move as he wished. Finally, the rheostats were returned to the observer's original setting for equal luminance, and the wheel was stopped. The observer matched the colours of the two papers with samples in a Munsell book, which was illuminated by a Macbeth Illuminant *C* lamp in an isolated area beside the wheel. (In some cases the Munsell book did not contain a sample saturated enough to match the coloured paper on the disk, in which case an estimate was made. The Munsell specifications are valid only for papers of equal luminance. At other settings of the rheostats the Munsell lightness values change. The hue and saturation values change also, but only to a minor extent in the range used in this experiment, since none of the combinations of paper and filter overlapped by more than 15 per cent.)

The Munsell values of the six pairs of papers are given in Table 1. All observers saw Mach bands in all the combinations, regardless of the relative brightness of the colours, from a distance of 4 feet (angular subtend 27 min). The pairs of colours in these cases were, in common terminology, red and green, red and blue, green and blue, blue and yellow, red and orange, and red and greyish green. From a distance of 40 ft. (angular subtend of each step 2·7 min) all the step tablets appeared to be continuous gradients of colour. At distances between 4 ft. and 40 ft., the observer saw either a continuous gradient of colour, or a series of bands of alternating colours, two bands for each step. At no distance did any intermediate step appear uniform, unless the observer was so close that a single step covered a substantial portion of his field of view. All this parallels the results from step tablets of varying brightness, where the observer sees either a smooth gradient or a set of alternating light and dark bands, depending on his distance from the display.

Table 1. SPECIFICATION OF THE COLOURS IN MUNSELL VALUES, WHEN THE VARIACS ARE SET FOR EQUAL BRIGHTNESS

Values are the average for the five observers

Case	Inner paper	Outer paper
1	5 *GY* 7/9	10 *R* 7/9
2	7·5 *PB* 4/16	5 *R* 5/8
3	7·5 *PB* 5/14	10 *GY* 6/8
4	7·5 *PB* 4/16	10 *Y* 5/4
5	10 *YR* 7/10	10 *R* 6/14
6	10 *GY* 7/4	10 *R* 6/12

Six observers were also asked to look at a continuous gradient of constant luminance, using the two subjectively most different colours of Table 1 (case 1), and describe what they saw. Three reported Mach bands and three did not. All reported Mach bands when one projector was turned off, giving a gradient of varying luminance.

There is no conflict between the results of these experiments and those of Thouless, and of Koffka and Harrower, since the experiments described here deal primarily with step tablets, and previous experiments dealt solely with continuous gradients. The conflict lies in the implications of the results and the conclusions to be drawn from them. It seems reasonable to assume that the mechanism causing Mach bands in the step tablet is the same as that causing them in the continuous gradient. In the *Limulus* the mechanism has been shown to be one of inhibitory interaction between neighbouring ommatidia[3]: in higher animals which can distinguish colour, the nature of the mechanism has not yet been elucidated. My results suggest that the mechanism acts on changes of chromaticity in the same way that it acts on changes of brightness. This could be reconciled with the results of Thouless, and of Koffka and Harrower, by saying that the action of the mechanism is below threshold for continuous gradients of constant brightness.

FORTHCOMING EVENTS

Monday, July 20

Zoological Society of London and the Anti-Locust Research Centre (at the Zoological Society of London, Regent's Park, London, N.W.1), at 10.30 a.m.—Symposium on "The Endocrine Control of Metabolism and Maturation in Insects".

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Assistant Lecturer or Lecturer (with a special interest in one of the following fields: plant geography, cartography, human geography, or industrial geography) in the Department of Geography—The Secretary, University College, Gower Street, London, W.C.1 (July 15).

Research Students or Assistants (with degrees in physiology, biochemistry, chemistry, zoology or allied subjects) in the Department of Physiology and Biochemistry—The Secretary and Registrar (Room 9), The University, Southampton (July 15).

Assistant Cataloguer (graduate with good academic qualifications and experience or training in librarianship) in the University Medical Library—The Registrar, The University, Manchester, 13 (July 17).

D.S.I.R. Research Students in Physics for research on nuclear magnetic resonance under Prof. J. G. Powles—The Registrar, University of Kent at Canterbury, Westgate House, Canterbury, Kent (July 17).

Reader/Senior Lecturer, a Lecturer and an Assistant Lecturer (preferably with previous experience and research interest in one of the following fields: electron physics, wave optics, cryogenics, nuclear physics, solid state physics, or microwave physics) in the Department of Physics—The Staff Officer, College of Advanced Technology, Gosta Green, Birmingham, 4, quoting Ref. 376/6 (July 18).

Research Assistant (well qualified in sociology and interested in its application to education) to the Professor of Education—The Registrar, The University, Keele, Staffs (July 18).

Assistant Lecturer or Lecturer in Pure Mathematics—The Secretary, Birkbeck College (University of London), Malet Street, London, W.C.1 (July 20).

D.S.I.R. Research Student (with a good honours degree in zoology) in the Zoology Section of the Department of Botany and Zoology, to join a group working on the ecology and physiology of protozoa with special reference to water pollution and purification—Dr. R. B. Purchon, Head of the Department of Botany and Zoology, Chelsea College of Science and Technology, Manresa Road, London, S.W.3 (July 20).

Laboratory Instructor (with a degree in chemistry and preferably some teaching experience, not necessarily in a university) in the Department of Physical Chemistry—The Registrar, The University, Leeds, 2 (July 20).

Biologist (Assistant Lecturer grade) to study growth characteristics of animal tumours by techniques which include autoradiography—The Director, B.E.C.C. Research Unit in Radiobiology, Mount Vernon Hospital, Northwood, Middlesex (July 21).

Senior Lecturer/Lecturer (dental, medical or science graduate with bacteriological experience) in Dental Microbiology—The Secretary, The London Hospital Medical College (University of London), Turner Street, London, E.1 (July 21).

University Librarian—The Registrar, The University, Manchester 13 (July 22).

Veterinary Officers (men and women aged at least 23, M.R.C.V.S. with at least one year's practical postgraduate experience) with the Ministry of Agriculture, Fisheries and Food, for posts in various parts of England—The Civil Service Commission, Savile Row, London, W.1, quoting Ref. 130/64 (July 24).

Lecturer in Clinical Psychology in the Department of Psychological Medicine—Secretary of the University Court, The University, Glasgow (July 25).

Post-Doctoral Research Fellow in Chemistry at Wollongong University College (an associated college of the University of New South Wales)—The Agent General for New South Wales, 56–57 Strand, London, W.C.2; and The Appointments Section, The University of New South Wales, Box 1, Post Office, Kensington, New South Wales, Australia (July 25).

Chair of Agriculture; and a Senior Lecturer-Reader in Agriculture at Makerere University College, Uganda—The Secretary, Inter-University Council for Higher Education Overseas, 33 Bedford Place, London, W.C.1 (July 30).

Lecturer in Agricultural Education; and a Lecturer in Agronomy (Oil Palm Research Division) at Njala University College, Sierra Leone—The Secretary, Inter-University Council for Higher Education Overseas, 33 Bedford Place, London, W.C.1 (July 30).

Assistant Lecturer/Lecturer in Cybernetics—The Academic Registrar, Loughborough College of Technology, Loughborough, Leicestershire, quoting Ref. 14/G (July 31).

Lecturer or Assistant Lecturer in Physiology at the University of Singapore—The Secretary, Inter-University Council for Higher Education Overseas, 33 Bedford Place, London, W.C.1 (July 31).

Lecturer (preferably with research interests in plant pathology) in Botany—The Registrar, The University, Manchester (July 31).

Lecturer (with an honours degree in pharmacy or equivalent qualifications, and preferably with a special knowledge and experience in pharmaceutical analysis and of the use of instrumentation methods) in Pharmaceutical Chemistry—The Secretary, The Royal College of Science and Technology, George Street, Glasgow, C.1 (July 31).

Research Fellow in the Department of Statistics of the Research School of Social Sciences, Institute of Advanced Studies, Australian National University, to work in the field of mathematical statistics and its application to other sciences—The Secretary, Association of Commonwealth Universities, Marlborough House, Pall Mall, London, S.W.1 (Australia and London, July 31).

Senior Lecturer in Medicine—The Registrar, The University, Sheffield (July 31).

Senior Lecturer or Lecturer in Anatomy; and a Demonstrator (Assistant Lecturer) in Anatomy—The Secretary, The Medical College of St. Bartholomew's Hospital, West Smithfield, London, E.C.1 (July 31).

Senior Lecturer (with a good honours degree in geography and either a higher degree or actively engaged in research leading to a higher degree, and preferably some lecturing experience) in Geography at the University College of Townsville, University of Queensland, Australia—The Secretary, Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (London and Brisbane, July 31).

Lecturer or Assistant Lecturer in the Computing Laboratory of the Department of Applied Mathematics—The Registrar, The University, Sheffield (August 1).

University Lecturer in Psychopathology—The Secretary of the Appointments Committee, Office of the General Board, The University, The Old Schools, Cambridge (August 1).

Lecturer/Senior Lecturer, and a Lecturer in Psychology at the University of Sydney, Australia—The Secretary, Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, August 14).

Research Associate (normally with some post-doctoral experience) in the Physics Department, to assist in work in the area of solid state thin film physics, and will be encouraged to initiate new projects in this field—The Principal, Royal Holloway College (University of London), Englefield Green, Surrey (August 15).

Senior Lecturer or Lecturer in the Department of Bacteriology, University of Ibadan, Nigeria—The Secretary, Senate Committee on Higher Education Overseas, University of London, Senate House, London, W.C.1 (August 17).

Chair of Organic Chemistry at the University of Western Australia—The Secretary, Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, August 22).

Lecturer or Assistant Lecturer (with prospect of advancement to Lecturer) in Pharmacology in the Department of Pharmacology and Therapeutics, Queen's College, Dundee—The Secretary, University of St. Andrews, Queen's College, Dundee (August 22).

Chair of Electrical Engineering at the University of Malaya, Kuala Lumpur—The Secretary, Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Malaya and London, August 31).

Mycologist (with a good honours degree in botany or equivalent with considerable postgraduate experience in mycology and plant pathology, an authoritative knowledge of the taxonomy of the phycomycetes, practical experience of abstracting and editing an abstract journal, and a working knowledge of at least two European languages other than English) at the Commonwealth Mycological Institute—The Director, Commonwealth Mycological Institute, Ferry Lane, Kew, Surrey (August 31).

Lecturer (preferably with field experience as a mine geologist or exploration geologist concerned with metalliferous deposits) in Geology—The Registrar, The University, Leicester (September 15).

Senior Lecturer and a Lecturer in the Department of Genetics—The Registrar, The University, Leicester (September 15).

Senior Tutor-Demonstrator in Biochemistry at the University of Sydney, Australia—The Secretary, Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, September 15).

Chair in Engineering Thermodynamics within the Department of Mechanical Engineering—The Registrar and Secretary, The University, Senate House, Bristol, 2.

Chemist or Biochemist (with a good honours degree) to work on the mutation of trace elements in man—The Administrator, Radiobiological Research Unit, Medical Research Council, Harwell, Didcot, Berkshire, quoting Ref. GEH/3.

Clinical Psychologist (Senior Grade) for duties which will include diagnostic and assessment work for the Psychiatric Departments at Salford Royal and Hope Hospitals—The Group Secretary, Salford Group Hospital Management, Committee, Fairhope Avenue, Eccles Old Road, Salford, 6.

Head (with high academic qualifications in physics with teaching and research or industrial experience) of the Department of Physics—The Principal, Huddersfield College of Technology, Huddersfield, Yorkshire.

Lecturer and an Assistant Lecturer in Pure Mathematics at the University of Uppsala, Sweden—Anthony Abrahams, 1 Garden Court, Temple, London, E.C.4.

Lecturers or Assistant Lecturers in Mathematics (two vacancies); and Lecturers or Assistant Lecturers in Applied Mathematics (two vacancies) in St. Salvator's College—The Secretary, University of St. Andrews, College Gate, St. Andrews, Scotland.

Post-Doctoral Fellow (spectroscopist, physicist or physical chemist) in the Department of Chemistry, to co-operate with Dr. A. J. Hyde on *the determination of molecular space-time correlation functions in liquids* using scattering from laser beams—Dr. Hyde, Department of Chemistry, The Royal College of Science and Technology, George Street, Glasgow, C.1.

Research Assistant (graduate in biology) in a newly formed Neurobiological Group (the work will be centred round cellular relations in peripheral nerves and spinal cord under normal and experimental conditions)—The Secretary, Institute of Neurology, The National Hospital, Queen Square, London, W.C.1.

Research Student (first- or second-class honours graduate in physics, chemistry or biochemistry) in Biophysics in the Department of Zoology, for biophysical research into the interaction of steroid hormones with micromolecules—Prof. I. Chester Jones, Department of Zoology, The University, Sheffield, 10.

Research Student (with a good honours degree in chemistry or physics or an equivalent qualification) in the Department of Physical Chemistry for work on the kinetics of capillary phenomena in collaboration with Prof. D. H. Everett and a post-doctoral fellow—The Administrative Officer (Mr. A. W. Honey), School of Chemistry, The University, Bristol 8.

Senior Electronics Technician in the Physics Department, to be concerned with the design and construction of electronic apparatus for research purposes—The Assistant Secretary, St. George's Hospital, London, S.W.1.

Senior Lecturer or Lecturer (with an honours degree in electrical engineering or physics and a sound knowledge of electronics, together with, if possible, experience of radar, guidance of missiles or telecommunications) in Electronics, to lecture to degree courses and specialized postgraduate staff courses and to supervise laboratory classes—The Registrar, Royal Military College of Science, Shrivenham, Swindon, Wiltshire.

TRAFFIC PROBLEMS AND INDUSTRIAL DEVELOPMENT IN BRITAIN

THE *South-East Study, 1961–81*, prepared by the Ministry of Housing and Local Government, was published at the end of March, together with a White Paper, *South-East England*, explaining how far the Government felt able to adopt the analysis of the problem and the proposal suggested in the *Study*. The commissioning of the *Study*, like the commissioning of the earlier studies of north-east England and central Scotland, and of the transport studies embodied in the Buchanan Report, is superficial evidence that the Government appreciates what is needed. Nevertheless, the successive White Papers and the debates on them in Parliament supply little concrete indication that the Government is prepared to take the necessary action, at least in time, and this impression is confirmed on every occasion when the Government is confronted with opportunities for immediate and effective action—as, for example, over the Morecambe Bay barrage and road scheme or the Liverpool Corporation's road scheme (see *Nature*, 203, 125; 1964).

To make sure that its traffic plans are adequate for the City's imaginative Shankland Plan, the City's Planning Department has commenced a traffic survey which will cost £75,000, and has shown that on its new road system alone the City of Liverpool must spend at least £100 million over the next twenty years, of which the City can provide £25 million. The rest must come from the Government; but for this the first opportunity of putting into practice the principles of the Buchanan Report, which the Government professes to support whole-heartedly, the Ministry of Transport at present intends to spend only £3 million over this twenty years on roads over the whole of Merseyside. Nor has the Ministry, while rejecting the regional proposals of the Buchanan Report, given any indication how the gap is to be filled, either at regional or at national level.

This weakness is outstandingly demonstrated in the way Mr. Marples rejected the Morecambe Bay barrage proposal of Mr. L. Leeming as an alternative route for the proposed extension northwards of the M6 motorway, but it is also illustrated in the White Paper, *South-East England*, and the debate on this Paper in the House of Commons on May 4. The *Study* assumes that between 1961 and 1981 the population of south-east England, which as defined in the *Study* lies south and east of a line between the Wash and Dorset, will increase by 3·5 million, of which 1·1 million will be due to net immigration. This will give Britain a population of at least 53 million in 1981, and, according to the White Paper, while not departing from its policy of channelling economic growth from the south-east to other parts of Britain, the Government accepts the basic objectives of the *Study*, including the need for new and expanded towns to accommodate up to 1·75 million people in ways providing effective relief for the pressures on London.

The Government also endorses the view expressed in the *Study* that high-quality agricultural land should not be taken for urban development wherever there is a practical alternative. In spite, however, of the attention directed to the heavy pressures on the green belt around London both in the *Study* and in a recent debate in the House of Lords, the White Paper will do little to remove misgivings already entertained in regard to that belt. It is clear that the Government is prepared to sanction certain inroads on the existing green belt, and the White Paper specifically states that the Minister of Housing and Local Government does not propose to approve proposals of local planning authorities for extending the green belt.

There is a reference in the White Paper to the possible effects on the region of the construction of a Channel Tunnel to which the Government has already agreed in principle. The plans for re-shaping the railway system to meet future demands are to include any proper through link between the Tunnel terminal and other parts of the country so that the benefits of improved communications with the Continent will be spread far beyond the south-east region itself. The White Paper also affirms the Government's intention, before reaching decisions on particular passenger closure proposals, to take full account of possible developments put forward in the *Study*. This at least is some advance on any earlier pronouncements relating to the Beeching Report, and, in particular, the Government now states that it will consider whether the possibilities of future development make it desirable that a line should remain available for future use if required.

It is recognized that the *Study* and its proposals raise many important issues on some of which public opinion outside the area must be consulted before decisions are taken. It is also clear that population pressures in the region are such as to demand planning now, even though the greater part of development in the expansion schemes will not take place until the 1970's. By determining the extent and location of public investment and industrial building, and by phasing the release of land for development in expansion schemes, it is claimed that the Government will ensure that the proper development of the south-east does not prejudice growth in other parts of the country. Its confidence in the organization for keeping under examination policies which have the most direct bearing on regional development is affirmed, as is its belief that regional planning can contribute greatly to the well-being and prosperity of Britain as a whole, and that this new programme and those already published and being implemented for Central Scotland and the north-east identify the special needs of the individual regions and contribute to the achievement and maintenance of a proper national balance (see *Nature*, 201, 458, 745; 1964).

In opening the debate on May 4, Mr. M. Stewart said that a national policy, such as this and other studies implied, called for a more stringent use of industrial development certificates, greater co-ordination in the activities of Departments, including the co-ordination of decisions on transport with general policy affecting the location of industry, and a thorough review of local government finance. Mr. Stewart stressed particularly the importance of finance and especially in regard to the acquisition of land, and in this connexion was the first of several speakers to refer to the siting of offices. This was admitted by Sir Keith Joseph, who followed, and he suggested that here automation might soon have an ameliorating effect. He also said that the Government was determined to move out of London as many as possible of the headquarters of civil servants: the decision to move the Post Office Savings Bank to Scotland was the latest large example. The Government was also determined to persuade firms that as much office work as possible should be moved out of London, and preferably out of the south-east region. The tough policy of the Board of Trade with regard to Industrial Development Certificates, which would continue, was a further factor towards the present disproportionate draw to the south-east.

For the rest, Sir Keith said that the Government recognized growth in the region was likely, and orderly provision for it must be made so as to improve life for all in the south-east, and in particular to ensure good housing, either in London or elsewhere, for all born in London or already living there. It accepted the need to relieve the pressure on London and to break the vicious circle of growth creating more growth. The strategy now was to provide attractive, vigorous big communities well outside London and well outside the green belt on a scale to cope with the foreseen overspill of more than one million. Moreover, these new communities would not consist of one section of the population but would comprise members of nearly every income group who could not find in London suitable accommodation at a price they could afford. He pointed out that more than 85 per cent of the acreage in the south-east was at present undeveloped, and by 1981, if all the proposals of the *Study* or their equivalent were accepted, more than 83 per cent would remain undeveloped. There would be careful consultation with all the planning authorities and local authorities concerned, but the Government hoped to reach a firm decision on the total to be provided by individual projects by the end of the year.

On office accommodation, he added that the first six months' working of the Location of Offices Bureau warranted the hope that in the next few months and over the short period of years ahead the Bureau might manage to offset by persuasion of individual offices a large part, if not all, of the increased office work in London presaged by planning permissions already given. No Government could allow the growth of office jobs to continue at its present rate. Finally, he admitted that possibly a new town type of corporation might be required to deal effectively with some of the new proposals and also that we needed an agency to acquire the land, make the plan, provide the services and then dispose of the land according to the plan, either by selling or letting to private or public enterprise. Re-zoning sufficient land for the entire period should suffice to give public and private authorities confidence that land would be available when required.

While there was some keen criticism of the adequacy of the Government's proposals in the debate, particularly in regard to the acquisition of land, the restriction of office buildings and co-ordination of policy, Sir Keith Joseph's statement embodied some definite assurances, and his speech was supported at some points by that of the Parliamentary Secretary to the Board of Trade, Mr. D. Price, who wound up for the Government. On immigration, Mr. Price observed that overseas immigrants, especially in the Greater London area, had been filling posts in the service industries which without them would have broken down. While it would be unrealistic to expect a substantial exodus of offices out of the south-east as a whole, he maintained a substantial move of offices from Central London to anywhere else in the south-east would be a great gain. He reiterated that the Government's proposals were consistent with its plans for the development of central Scotland and north-east England and elsewhere.

There were five factors safeguarding development outside the south-east. First, the developing regions where the needs were greatest would have a long start. Programmes were already being implemented for central Scotland and the north-east of England, whereas the major schemes in the south-east would not make their full demands for capital investment and labour until the 1970's. Further, the Industrial Development Certificate policy would continue to give first priority to the development districts, and, subject to this, would seek to get industry out of the main conurbations into new and expanded towns which are receiving their populations. Next, the north-east of England and central Scotland which, with 13 per cent of the population, had 18 per cent of the public investment programme, would continue to receive such priority for some years. Present inducements to attract industry to development districts would remain and the growth zones in both these regions had received assurances of a sustained and continued effort. Mr. Price saw a fifth safeguard in the extent to which the town expansions in the south-east would generate their own employment. Finally, he said that the study teams for Wales, the west midlands and the north-west had reached the stage of detailed local consultations. There would be comprehensive regional studies covering changes in population, industrial structure and employment, land use and urban renewal and communications, and a study for the East and West Ridings of Yorkshire was being considered by the Secretary of State for Industry and Trade. No decisions had yet been taken on the places suggested for expansion in the *South-East Study*; but while Mr. Price declined to give a flat undertaking that Industrial Development Certificates in these towns would not be given to firms from the north or west, he undertook that they should be limited essentially to firms from London.

However reasonable the Government's position may appear as presented in the White Paper and in this subsequent debate, confidence is badly shaken by its failure to take effective action on the Buchanan Report and the co-ordination of traffic policy with other national needs. The *South-East Study* stands at marked issue, for example, with many recommendations of the Beeching Report to which the Minister of Transport has repeatedly declared his support, while the Minister's short-term policy on road transport has been severely criticized by Sir Robert Matthew, professor of architecture in the University of Edinburgh. Mr. F. Medhurst, in a university extension lecture, has pointed out that a regional development authority set up by the Government could be expected to execute the proposed Morecambe Bay barrage scheme. The scheme involves the creation of a freshwater lagoon, a barrage able to carry a motorway and railway tracks, and a dozen square miles of salt marshes would be cleared of salt and made available for agriculture.

These factors would accordingly involve the River Board, the Ministries of Transport and Agriculture, if not the Ministry of Industry and Trade also, as well as British Railways, the Lancashire County Council and Manchester Corporation. The prescience of Mr. Medhurst's comment that each of these would be likely to examine the scheme in a particular aspect and against limited alternatives is demonstrated as clearly by Mr. Marples's subsequent brusque rejection of the Plan as by the inadequacy of the Government's whole approach to such problems. Mr. Marples declined to consider it as an alternative to the inland route for the motorway to Scotland and intends to proceed with the route running east of Shap through Tobay.

Mr. Marples did not dismiss entirely the coastal route over the barrage, but while he emphasized the importance of the time-factor, he was more than a little naïve in suggesting that the barrage route must be considered as a regional project. Mr. Medhurst's lecture makes nonsense of that idea and Mr. Marples's hasty refusal should stimulate the technical colleges and universities in the north-west to take up urgently Mr. Medhurst's suggestion and undertake some of the research needed within the scope of the scheme, presenting the findings to the Government with a request for combined regional action. Meanwhile, Mr. Marples's decision should be firmly challenged, and every effort made to expedite the surveys and enquiries which are necessary before technical decisions on the scheme can be reached. It is also essential that the full implications of the scheme, not only in respect of road transport between England and Scotland but also no less in respect of water supply for Lancashire, and the revival of industrial west Cumberland, not forgetting the marginal implications in respect of agriculture and land utilization, should be brought to public understanding. If such a scheme is to be rejected it should be in a rational perspective and not through departmental myopia.

A GREAT ENGLISH BOTANIST

Joseph Dalton Hooker

Botanist, Explorer, and Administrator. By Dr. W. B. Turrill. (British Men of Science.) Pp. xi+228+25 plates. (London: Thomas Nelson and Sons, Ltd., 1963.) 21*s.* net.

JOSEPH DALTON HOOKER was twenty-two at the start of his Antarctic voyages in 1839: in 1911 his botanical work came to an end only a few months before his death at the age of ninety-four. From that long life one can select four chapters for comment: Antarctic botany, Indian botany, the association with Charles Darwin, and the directorship of Kew. Any one of these would rightly give Hooker a place in the series, *British Men of Science*, and Dr. Turrill's achievement in condensing all this, and more, into 228 pages is considerable. Author, editor and publisher all earn our gratitude for presenting, at a reasonable price, this concise and interesting account of a great botanist.

The Antarctic and Indian phases are well summarized and numerous passages in Hooker's own words add authentic flavour to the story of the discomforts and the rewards of pioneer botanical work in the field. Hooker not only wrote vividly of his experiences, he was always busy with his sketch books, and selected pages from these provide the most attractive illustrations in this volume. In telling us of Hooker and his work, Turrill says enough about the items he selects for comment to make them botanically informative. For example, Hooker's account of the Kerguelen cabbage (*Pringlea antiscorbutica*) is brought up to date with more complete information on its distribution and vitamin C content. Throughout, there are frequent references to more recent evaluations of Hooker's data, so that the student who reads these pages is in no danger of coming away with a lot of out-of-date ideas. Not that Hooker's views on classification or plant distribution need much modernization; perhaps only his positioning of the gymnosperms (as on pp. 81–82) now seems grossly inaccurate.

One amusing point in the preparation of this review may be mentioned. I found (p. 60) what seemed to be a very surprising statement: that the upper limit of *Pinus longifolia* (= *P. roxburghii*, the *chir* pine) in Sikkim was at 2,500 ft. This seemed incredibly low. Surely there must have been a slip somewhere? But no; Hooker carefully records that it is restricted to this altitude in southern Sikkim because it is a plant of the dry hills: elsewhere it may ascend to 7,000 ft., but only where its habitat is found at that height. Southern Sikkim above 2,500 ft. is too wet for this species. Hooker was not known as an ecologist: the term was not yet in use.

The enigma of Hooker's life, as Turrill brings out quite clearly, lies in the nature of his scientific thinking between 1844, when he read Darwin's preliminary essay, and 1859, when the publication of *The Origin of Species* threw Darwin's views on evolution open for public discussion. Excerpts from Hooker's writings of this period are quoted, and these show that he was by no means fully satisfied with the idea that species were immutable, yet for practical purposes he did accept them as fixed entities. Did he feel obliged, out of loyalty to Darwin, to suppress his own thinking on this subject? Or was he, in fact, so fully occupied with prosecuting his practical classificatory work that the theoretical side did not greatly concern him? Hooker was Darwin's friend and his adviser on botanical matters and provided him with many taxonomic (and phytogeographical) data. They were in constant communication. One can scarcely avoid the conclusion that Hooker was content to stick to taxonomy and leave evolution to Darwin. When Turrill (p. 212) seeks reasons why Hooker did not, after his open acceptance of Darwin's views, "attempt to work out a classification of plants on evolutionary principles", he surely misses a simple point. Darwin had provided the evolutionary explanation, in acceptable terms, for Hooker's taxonomic facts. What need was there to alter the taxonomy?

Turrill's own association with Kew ran from 1909 until his death in 1962 and, although he met Hooker but once, he lived surrounded by the Hookerian tradition. Naturally, therefore, he gives due attention to Hooker's achievements as director of Kew. Yet here one is conscious of the biggest gap in this biography. Hooker's lasting influence on Kew was not in re-organizing the Gardens' water supply, not in the extension to the Herbarium nor in planting the Cedar Avenue. He did not build Kew with pipes and bricks, nor even with plants: but with men. Daniel Oliver, J. G. Baker, Sir William Thiselton-Dyer, W. Botting Hemsley, Otto Stapf—these were the men Hooker gathered around him at Kew, yet they scarcely figure in these pages. W. B. Turrill was in the direct line of succession; it is strange that he failed to recognize in them the final proof of Hooker's greatness.

B. L. BURTT

HAZARDS OF SMOKING

Smoking and Health

Report of the Advisory Committee to the Surgeon-General of the Public Health Service. (U.S. Department of Health, Education and Welfare: Public Health Service.) Pp. xviii+387. (Princeton, N.J.: D. Van Nostrand Company, Inc.; London: D. Van Nostrand Company, Ltd., 1964.) 27*s.* 6*d.*

IN 1963 the Surgeon-General of the United States Public Health Service set up an advisory committee to undertake a comprehensive review of all data on smoking and health. This book represents the fruits of their labours. It is in fact the latest in a series of evaluations of the evidence relating smoking and health which have been published during recent years. It covers much the same ground as the report on the same theme published in Britain in 1962 by the Royal College of Physicians and reaches the same general conclusions: cigarette smoking is a hazard to health and, more particularly, is an important cause of lung cancer in men and of chronic bronchitis. It is also associated with coronary artery disease and with a number of other less common diseases, although it is not certain in these cases if the association is causal.

The book is in two parts. In the first part the methodology of the study is described and the main conclusions summarized. The evidence on which these conclusions are based is set out in detail with numerous references to the original literature in the second part. The large amount of published material available is dealt with critically from both a general point of view and on the basis of disease categories. It is not possible here to give more than a rough outline of the ground covered. Separate chapters are concerned with consumption of tobacco products in the United States, chemical and physical characterization of tobacco and tobacco smoke, the pharmacology and toxicology of nicotine, mortality of smokers, and the relation of smoking to cancer, other respiratory diseases, cardio-vascular disease and other conditions. Beneficial effects of tobacco, psycho-social aspects of smoking and the morphological constitution of smokers are also considered.

The great bulk of the report is taken up with consideration of the epidemiological investigation of the effect of smoking on health. In seven large prospective investigations it has been constantly found that death-rates in general for cigarette smokers are higher than for non-smokers, and are substantially higher for cancer of the lung and other forms of cancer of the upper respiratory tract, for bronchitis and for coronary artery disease.

Most general interest will probably attach to the findings on lung cancer. A careful review of the evidence leaves the committee in no doubt that cigarette smoking is an important element in the causation of lung cancer in men, and while it recognizes that it cannot be the only cause, it gives it as its opinion that the magnitude of the effect of cigarette smoking far outweighs all other factors. Twenty-nine retrospective and seven prospective investigations all agree in showing a higher incidence of lung cancer among smokers than non-smokers, and the incidence increases regularly with the amount smoked. This evidence is supported up to a point by pathological studies of the tracheobronchial tree of smokers and non-smokers, and by the evidence from several laboratories that tobacco smoke condensate is carcinogenic to the skin of several animal species. A number of carcinogenic hydrocarbons and heterocyclic compounds have also been detected in cigarette smoke although, contrary to the report, only one has actually been isolated. The committee clearly feels that the smoke exerts its effect, in the main, by a direct carcinogenic action on the lung tissue, possibly through the agency of the polycyclic hydrocarbon and heterocyclic carcinogens contained in it, but it recognizes that the experimental evidence for this view is not conclusive. Tumours have not yet been produced in the lungs of experimental animals by direct inhalation of cigarette smoke, although they have been obtained in a few instances by direct application of smoke condensate. In addition, the amounts of the hydrocarbon carcinogens so far detected in cigarette smoke appear to be insufficient by a large factor to account for the activity of the smoke condensate towards the skin of experimental animals. However, the likelihood that hydrocarbon carcinogens may be involved is increased by the recent demonstration by Shabad that epidermoid carcinoma can be produced in the lungs of rats by intubation of a hydrocarbon carcinogen absorbed on carbon particles. Cigarette smoke has also been found to contain substances with tumour-promoting properties, and these may enhance the effect of the small amounts of carcinogens which are present. The effect of damage to the defence mechanisms of the respiratory tract by tobacco smoke must also be taken into account.

The other main diseases with which cigarette smoking appears to be related are bronchitis and coronary artery disease. In the case of bronchitis, the association is so strong as to be considered one of direct cause and effect, and the report states categorically that cigarette smoking is the most important cause of chronic bronchitis in the United States. In this the American experience differs somewhat from that in Britain, where other factors besides cigarette smoke are considered in the report of the Royal College of Physicians to play a part in the development of chronic bronchitis. It has been established also, in a number of studies, that male cigarette smokers have a higher death-rate from coronary artery disease than non-smoking males, but it is uncertain whether there is a causal relationship. A number of other factors are associated with coronary artery disease and it is not easy to disentangle the effect of any one.

The book is well produced; there are very few misprints and the tables and diagrams are excellent. An index would have been useful. W. CARRUTHERS

ANIMAL SOURCES OF HUMAN DISEASE

Diseases Transmitted from Animals to Man

Compiled and Edited by Dr. Thomas G. Hull. Fifth edition. Pp. xxii + 967. (Springfield, Ill.: Charles C. Thomas, 1963.) 17.75 dollars.

THIS useful book, well known since its first publication in 1930, appears now, in its fifth edition, with the collaboration of 32 specialists who have contributed to it one or more chapters. Thus the book now contains authoritative articles on a wide variety of subjects, all of which are important to both medical men and veterinarians.

In Section 1, there are articles on the diseases of domesticated animals and birds and on some of the diseases of wild animals and rodents. Section 2 deals more specifically with the diseases of rodents and wild animals, but includes some diseases of domesticated animals. Section 3 is devoted to the relationships between diseases of man and those of other animals, this important subject being considered under the headings of: animal diseases of minor public health importance; human diseases that are spread by other animals; animals that are passive carriers of pathogenic organisms; and the part played by different animals and birds in relation to diseases of man.

It will be realized that a brief review cannot give an adequate idea of the large number of diseases considered. Most of the space is given to bacterial, viral and fungus diseases and only one chapter, about 10 pages long, is specifically given to diseases caused by parasitic animals (Protozoa and Helminths). This chapter, however, carries all the authority of its author, Prof. Faust, and parasitic animals inevitably have their place in the final chapter on the part played by different animals and birds in diseases transmitted to man.

It is, indeed, in this final chapter, written by Dr. Hull, that the theme of the book is epitomized; and the tables in it, which list the large number of diseases that may be transmitted to man from other animals, will be of value to medical men and veterinarians. The layman who keeps dogs, cats, birds and other pets should also be interested but he will not, one hopes, be unduly alarmed by the possibilities here outlined. Dr. Hull names 36 diseases that may, in various parts of the world, be transmitted to man, either directly or indirectly, from the horse, 57 from the cow, 47 from the hog, 48 from the sheep and goat, 65 from the dog, 39 from the house cat, 32 from rats and mice, and 27 from the fowl and other poultry. He also gives a list, 2½ pages long, of diseases that may possibly be transmitted to man from wild animals and birds. It should be realized, however, that many of these diseases are repeated in each of the lists, so that the total number of diseases is correspondingly reduced. A final list, 9 pages long, gives a useful summary of all the diseases, with their ætiological agents, their common animal hosts and the usual methods by which man may be infected.

One purpose of the book is to provide a common meeting ground for the physician, health official, veterinarian and research worker, and in this it should succeed. It will help, one hopes, to foster the movement, now gathering force, towards close co-operation between the medical man, the veterinarian and the biologist in the fascinating field of comparative medicine and surgery. Some readers may find that the space given to some of the diseases considered might have been extended and that given to others shortened, but opinions about this will vary according to the special interests of the reader and the importance of certain diseases in particular parts of the world. The scope of the book is, it should be remembered, world-wide, and the 32 contributors have been given considerable freedom in their treatment of the subjects allotted to them.

The book is well printed on thick, glossy paper and this makes it rather a heavy book to handle; but no doubt this paper helps the reproduction of the illustrations, most of which are photographs of lesions in man and other animals. Many of these will be valuable to practising medical men and veterinarians. The general production of the book maintains the high standard that we have learnt to expect from its publisher.

G. LAPAGE

ABSORPTION OF LIPIDS FROM THE INTESTINE

Biochemical Problems of Lipids

Edited by A. C. Frazer. (B.B.A. Library, Volume 1.) Pp. ix+474. (Amsterdam, London and New York: Elsevier Publishing Company, 1963.) 130*s*.

THIS volume contains the fifty-eight papers read at the seventh international conference on "Biochemical Problems of Lipids", held in Birmingham during June 24–27, 1962. The main theme was the mechanism of fat absorption from the intestine. Papers concerned with this subject were classified thus: (1) intraluminal aspects of fat absorption; (2) structural aspects of the intestinal cell and absorption studies; (3) enzymatic aspects of intestinal lipid metabolism; (4) chylomicrons and lipoproteins.

In Section 1 there is frequent reference to the use of thin-layer chromatography for detecting the products of enzymatic hydrolysis of triglycerides and identifying individual bile acids. The role of bile in the solubilization of synthetic hydrocarbons and dyestuffs has also been investigated, as have the effects of diversion of the bile on the recovery of lipids in the thoracic-duct lymph. In addition, there are papers on the amount and composition of the fæcal fats of several species, which have been examined with particular reference to the influence of the intestinal bacteria.

There are important papers in Section 2 dealing with the fine structure of intestinal epithelial cells and particularly with the brush border, as observed under the electron microscope. Results obtained by different groups have been presented in support of possible mechanisms of lipid absorption from the intestine. It appears that at present there is still a great deal of uncertainty regarding the nature of this process. Opinion seems to be rather evenly divided in favour of absorption of lipid droplets by pinocytosis on one hand, and of a highly dispersed molecular or micellar species on the other.

In Section 3, the main line of research concerns the re-synthesis of triglyceride in the intestinal mucosal cells. It seems to be generally accepted that the most important pathway in this tissue involves the condensation of monoglyceride with two molecules of long-chain acyl-coenzyme A. Thus intestinal mucosa differs from other tissues in which triglyceride synthesis begins with the acylation of L-α-glycerophosphate.

One of the papers in Section 4 deals with the composition of rat thoracic-duct lymph as a function of the nature of the dietary triglyceride. Lipids containing fatty acid radicals of short and intermediate chain length ($C_4 - C_{10}$) are not found in the lymph draining the intestine, following oral administration of the triglycerides of these fatty acids; on the other hand, the long-chain component fatty acids ($C_{12} - C_{18}$) do appear in the lymph under comparable experimental conditions.

Only about two-thirds of the papers presented deal with the main absorption theme. The rest are divided into two additional sections: (5) mitochondrial and other aspects of lipid metabolism, and (6) wider aspects of lipid metabolism. Some of the most interesting papers in the whole volume are to be found in these two sections. Thus in Section 5 there is an excellent account of the role of lipids in mitochondrial electron transfer and oxidative phosphorylation; also a very careful investigation of the cause of fatty livers in rats following injection of either ethionine or puromycin.

In Section 6 there are important investigations on the lipids of the erythrocyte membrane. The solubilization of these lipids has been examined following treatment with hypotonic saline and various hæmolytic agents. The lipid composition of the erythrocyte membranes of different species has been determined and incorporation of lysolecithin and linoleic acid into the lecithin component has been observed. Other papers of interest deal with the synthesis of unsaturated fatty acids by yeast, the effect of essential fatty acids in the diet on the lipid composition of rat heart and the metabolism of linoleic acid in rat liver.

Each paper is followed by a discussion of variable length, but only about half the papers contain a summary. A subject index has been provided, which seems to have been compiled exclusively from words appearing in the titles; similar topics are thus not necessarily brought together.

This volume does not attempt to give a connected account of the absorption of lipids from the intestine. Instead, it presents a series of investigations designed to solve some outstanding problems. For this reason, the book will probably appeal to lipid workers, whatever their specialized interest, but it is doubtful to what extent it will be read by others.

C. LONG

HIGH-PRESSURE PHYSICS AND CHEMISTRY

High Pressure Physics and Chemistry

Edited by R. S. Bradley. Vol. 1: Pp. xi+444. 100*s*. Vol. 2: Pp. xii+361. 80*s*. (London: Academic Press, Inc. (London), Ltd.; New York: Academic Press, Inc., 1963.)

THE progress of the physical sciences may be likened to an incoming tide, the advancing waters presenting an uneven front but the general level rising at a fairly uniform rate; new techniques and discoveries in a particular sector invariably generate points of growth in neighbouring sectors and thus contribute to the overall advance.

The history of high-pressure technology affords an excellent example of this process. Improvements in experimental methods, the specific demands of industry and the need to confirm the predictions of theory have, in turn, stimulated activity in the field. In the latter half of the nineteenth century, the work of the great French physicists Amagat and Cailletet was associated with the problem of the liquefaction of the so-called 'permanent gases'. It was followed in the early years of this century by the pioneering work of Le Chatelier and Haber on the effect of pressure on chemical equilibria and, in particular, on the synthesis of ammonia. During the period 1912–60, P. W. Bridgman advanced the subject by greatly extending the range of pressure accessible for experimental observation and by measuring the physical properties of numerous liquids and solids up to pressures of several hundreds of thousands of atmospheres. The latest step forward has carried observations into the range of pressure found within the Earth and in astral bodies.

Since pressure is one of the thermodynamic functions which determine the state of a material system, its effects are not confined to any one branch of science. The literature is scattered and it is by no means easy to obtain a coherent picture of a subject which is advancing rapidly on many fronts. Workers in the field and students will, therefore, welcome a series of reviews, edited by R. S. Bradley, in which important aspects of recent work are summarized and accompanied by bibliographies. The scope of *High Pressure Physics and Chemistry* includes an account of the methods of generating and measuring high pressures, descriptions of apparatus and experimental techniques and the applications of pressure to the investigation of reaction rates, chemical equilibria, the physical properties of matter and the Earth sciences.

The discoveries which have aroused greatest interest in recent years are those resulting from the combined use of high temperatures and high static pressures, and those in which transient high dynamic pressures have been applied by shock-wave methods. In the former, a number of solid–solid transitions have been investigated, including boron nitride–borazon, silica–coesite and graphite–diamond, and also certain phase changes in metals which are presumed to involve an electron transition; this work is well summarized in two contributions by R. S. Bradley and W. Paul respectively. In the latter, electrical and metallurgical effects have been observed up to pressures as high as 10^6 atmospheres and new $P-V$ data have been obtained over a similar range.

The theory and application of shock-waves are dealt with in some detail by G. E. Duvall and G. R. Fowles, and the problem of an equation of state applicable to ultra-high pressures by L. Knopoff. The development of shock-wave methods for determining equations of state allows direct comparisons of pressure–density relations to be made and is affording important information on the composition of the Earth's interior. Thus it has been shown that the density of iron is somewhat larger than the densities in the Earth's core and that a mean atomic number of about 23 is consistent with core conditions.

In giving a survey of the applications of high pressures to the Earth sciences, P. J. Wyllie points out that we are now passing through a period of reconnaissance—"a reconnaissance of possible processes that could lead to the formation of a particular assemblage of minerals with specific textural relationships"—and that this must be followed by a period in which more precise data are sought, particularly in the higher pressure–temperature ranges. The possibility which now exists of reproducing a geological process within a pressure vessel is opening up new fields in experimental petrology.

It would be wrong to conclude this review without a reference to contributions by B. F. Dodge and S. D. Hamann on the effect of pressure on chemical equilibria in gaseous and condensed systems and on reaction rates. The aim of the authors is a very practical one, that is, to provide a basis for calculating the conversion at equilibrium of a reactant, either in a single reaction or in a set of simultaneous reactions as it is influenced by pressure, predicting whether or not a proposed new reaction is thermodynamically possible and under what conditio of temperature and pressure it could be expected to gi favourable yields, and determining the role of pressu on the rates of homogeneous liquid phase reactions.

Dr. Bradley has been fortunate in enlisting the c operation of so many distinguished workers in the hig pressure field in the preparation of his book, and he is to congratulated on the successful manner in which he h discharged the onerous duties of editor.

D. M. NEWITT

PLASMA PHYSICS

The Theory of Plasma Waves

By Prof. T. H. Stix. Pp. x+283. (McGraw-Hi Advanced Physics Monographs Series.) (New York an London: McGraw-Hill Book Company, Inc., 1962.) 76s

THE theory of waves in a plasma may be said to hav originated with the pioneering papers of Langmui and Tonks in the late 'twenties. Interest in the subjec was revived after the Second World War because of it importance in the problem of thermonuclear fusion— the 'philosopher's stone' of plasma physics. Since the a vast number of papers on the subject of plasma wave have appeared, but up to the present these lay scattere among the pages of many scientific journals. In thi beautifully produced book the author had collecte together as an organic whole the many complex topic connected with the behaviour of waves in plasmas contained in these papers. The book is a model of expositio and, in my opinion, a classic among the extensiv literature on the physics of plasmas.

The book deals with small-amplitude waves in a cold plasma, boundary value problems in plasma waves, and the theory of waves in a hot plasma—both in the absence and in the presence of a magnetic field. In the first chapter the topological genus of the wave-normal surface is discussed and in the succeeding chapter the small amplitude waves are analysed more fully in terms of the now well-known diagram due to Clemmow, Mullaby and Allis. Here will be found derived in a logical sequence the hydromagnetic waves of Alfvén and Aström, ion-cyclotron waves, the Appleton–Hartree dispersion relation and the so-called 'electrostatic waves'.

The flow of energy associated with the passage of plasma waves is discussed here and such concepts as group velocity and ray optics are admirably treated. The author also introduces the notion of 'accessibility' in a plasma of high density.

Problems of stability of equilibrium plasma configurations associated with the names of Kruskal and Schwarzschild are regarded as boundary value problems in plasma waves—though the classical methods of Kruskal and Schwarzschild are faithfully followed.

An interesting account is given of the plasma models with discrete structure and especially those due to Dawson and van Kempen, and also of the 'trapping' of charged particles in the potential wells of the electric field of the plasma waves. Mention is also made of the important work of Bunemann of two-stream instability using a charged-sheet model of a plasma.

The major portion of the book is concerned with a 'hot' plasma; there are clear expositions of the physical nature of Landau damping, that is, the phenomenon of the absorption of energy from a plasma by a collisionless process, and of the Nyquist criterion for instability. A chapter devoted to the theory of small amplitude waves in a hot plasma in the presence of a magnetic field includes such topics as cyclotron damping, magnetic trapped particle modes, concluding with a discussion o the solution of Boltzmann's equation for a hot plasma. This covers damped, stable and undamped waves. In the final chapter, the author considers the propagation of waves in the case where both the plasma density and magnetic field are inhomogeneous with the associated phenomenon of reflexion and absorption of these waves in certain critical cases.

An interesting feature of the book is the admirable collection of examples (of which there are nearly one hundred) at the end of each chapter. Some contain hints for the proof of theorems enunciated in the text, others serve as useful illustrations of points discussed therein. There is also a comprehensive bibliography. The author is to be congratulated on this excellent treatise, and every plasma physicist will feel indebted to him for this. It will surely find a place on the library shelves of every serious student of plasma physics.

V. C. A. FERRARO

SOLVING FIELD PROBLEMS

Analysis and Computation of Electric and Magnetic Field Problems

By K. J. Binns and P. J. Lawrenson. Pp. xiv+333. (London and New York: Pergamon Press, 1963.) 84*s*. net.

FREQUENTLY an engineer or physicist has to solve a field problem involving complex mathematical analysis. More often than not it is difficult to find someone who can understand the problem and advise on the best way of solving it. Although the situation is improving it is still a rare department that has a highly competent engineer–mathematician on its staff who can advise others on the best methods for tackling specific problems.

This book goes a long way towards providing many of the answers that are required. It is directed at practising engineers and physicists, as well as students seeking a better understanding of field problems. The standard of mathematics required to start reading the book is within the syllabus of a normal engineering degree; where more advanced mathematical topics are introduced, they are fully explained in the text. Throughout the book the emphasis is on the physical significance of the mathematics, and to this end practical examples are used wherever possible.

The book is divided into four parts. Part 1 serves as an introduction to the rest of the book; it deals with basic field theory and the methods of calculating force, inductance and capacitance from a knowledge of the field distribution. Part 2 is concerned with images and direct methods of solution, much along the lines of the book by Hague. However, in addition, attention is directed to the solution of the Laplace equation in Cartesian coordinates, and where the method of images is used the solutions are expressed in a convenient complex variable form.

The largest part of the book, Part 3, deals with transformation methods, and the authors claim that their treatment of the subject is the most comprehensive available. This certainly appears to be so, for in the five chapters in this part the authors present in a most clear and concise fashion a vast amount of transformation theory. The first chapter in this section presents the basic transformation theory leading up to the transformation equations. The second chapter is concerned with curved boundaries and the following chapter with polygonal boundaries. There follows a chapter on the application of elliptic functions and finally one on general considerations. Of particular interest in this third part are the treatments of line and doublet sources, the transformation of regions exterior to finite polygonal boundaries and a most useful technique for the direct numerical integration of functions of a complex variable, which permits solution of problems involving boundaries of greater complexity than is otherwise possible.

In Part 4, the powerful finite-difference methods are discussed. Again, the treatment is from first principles, and practical problems serve as examples for the application of the techniques evolved. The practical advice on the actual methods to be adopted is most useful. The section devoted to convergence and the optimum choice of parameters to provide the most rapid convergence possible for any given problem is probably the best so far available anywhere in the literature. Other topics include gradient boundary conditions and errors. In the conclusion to this part, the authors make the point that if a digital computer were used, it might be possible to reach the solution to a problem much more quickly by means of finite-difference methods than by analytical methods—that is, if an analytical solution exists anyway.

The appendixes include a useful list of transformations, many of which have not previously been published. These, for the most part, involve elliptic functions.

Every chapter ends with two lists of references. The first refers to specific points in the text, and the second indicates related literature which could be of interest. In addition, at the end of the book, an extensive bibliography is included.

Even if one knows a method for solving a specific problem one would be well advised to look within the covers of this book to ensure that no better method exists for the solution. This is an excellent volume, which is certain to prove most popular. The authors are to be congratulated.

E. M. FREEMAN

PHOTOCHEMISTRY

Advances in Photochemistry

Vol. 1. Edited by W. Albert Noyes, jun., George S. Hammond and J. N. Pitts, jun. Pp. ix+443. (New York and London: Interscience Publishers, a division of John Wiley and Sons, 1963.) 125*s*.

DURING the past few years, there has been a rapid rise in the number of *Progress in . . .*, *Advances in . . .*, *Aspects of . . .*, and other such series about various topics in chemistry. As a result, with any new series of this general type, the reviewer must not only consider the merits of the particular volume being discussed, but also whether the series itself fulfils any real need.

The growth of virtually all aspects of photochemistry has been particularly marked during the past fifteen years. This has undoubtedly been as much due to the development of new analytical techniques (for example, gas chromatography) as to developments in spectrometers and progress in spectroscopy generally. Considerable advances have been made in the elucidation of mechanisms of many photochemical reactions and progress has also been made in determining the nature of the intermediate excited states resulting after the absorptions of radiation. A surprising number of compounds obtainable only with extreme difficulty by conventional synthetic procedures can now be made simply by photochemical methods, and often on quite a reasonable scale. Indeed, the first really large-scale manufacture of materials using a photochemical reaction has recently been undertaken.

Few of these developments have yet appeared in chemical text-books, and surprisingly few works specifically devoted to photochemistry exist. While several reviews and articles on various photochemical topics have been published, they are very widely scattered. Thus we see that there is little doubt of the real need of a series of reviews on photochemistry.

Volume 1 of *Advances in Photochemistry* consists of nine chapters, and contains, in addition, author and subject indexes. The first chapter on "The 'Vocabulary' of Photochemistry", by J. N. Pitts, jun., F. Wilkinson and G. S. Hammond, deserves to be read not only by all practising and intending photochemists but also by all undergraduates specializing in chemistry. It presents a clear and remarkably concise account. In the space of some twenty pages the terms for symmetry, and state symbols for the description and presentation of spectra, are considered and discussed, as are selection rules and chemical processes. Even such topics as high-pressure, medium-pressure and resonance lamps are covered. These terms are, of course, obvious (or even trivial) to the expert, but often present very real difficulties for the novice and undergraduate.

This chapter is followed by "The Photochemistry of Aromatic Hydrocarbon Solutions" by E. J. Bowen; "Photochemical Gas Phase Reactions in the Hydrogen–Oxygen System" by D. H. Volman; "Photochemistry of Cyclic Ketones" by R. Srinivasan; "Addition of Atoms to Olefins in the Gas Phase" by R. J. Cvetanović; "A New Approach to Mechanistic Organic Photochemistry" by H. E. Zimmerman; "Isotopic Effects and the Mechanism of Energy Transfer in Mercury Photosensitization" by H. E. Gunning and O. P. Strausz; "Photochromism" by R. Dessauer and J. P. Paris; and "Photochemical Rearrangements of Organic Molecules" by O. L. Chapman. These chapters are of a high standard, as is to be expected, for their authors have all made important contributions to various aspects of photochemistry. The range of topics is very wide and it is unlikely that more than a very few will be equally interested in all chapters. This is by no means a disadvantage and could lead to much useful cross-fertilization.

Even though the range of subjects in Volume 1 is wide, there are still large areas of photochemistry not mentioned. We are promised that this series will cover topics ranging from the elucidation of spectra of polyatomic molecules to the photochemistry of biological systems in plants and animals. Volume 2, which will follow Volume 1 in quick succession, will doubtless include many of those areas which have not appeared in the first volume. Thereafter, about one volume should appear each yaer.

Advances in Photochemistry is well produced and seems to be remarkably free from misprints, etc. The structural formulæ, especially in the long final chapter, are very clear and beautifully reproduced (which makes a few formulæ in an earlier chapter, which appear to have been drawn by only a semi-skilled hand, look even more out of place). The book can be strongly recommended to all photochemists and will certainly find a place in all science libraries. It is a pity that its price will probably prevent its purchase by a wider audience. The editors, Profs. Noyes, Hammond and Pitts, are to be congratulated on their choice of authors and topics for this first volume, which augurs well for the future of this series.

THE SEA AS AN ENVIRONMENT

Marine Distributions

Edited by M. J. Dunbar. (The Royal Society of Canada Special Publications, No. 5.) Pp. viii + 110. (Toronto: University of Toronto Press; London: Oxford University Press, 1963.) 40*s*. net.

THE publication in book form of a series of papers, the substance of which has been, or probably will be, published in the usual journals, must have behind it a strong belief in the need to direct attention to the interrelationships of the individual subjects. It was the belief that emphasis should be placed on the interdisciplinary nature of oceanography that led to the organization of a symposium in June 1962 at which these six papers on aspects of marine distribution were read. The symposium was to serve, in particular, to introduce the *Serial Atlas of the Marine Environment*, which was sponsored jointly by the U.S. National Academy of Sciences and the Royal Society of Canada.

The object of the *Serial Atlas*, which is described in the first paper, is to provide a new type of journal in which distributional investigations from all disciplines will be published. By plotting these distributions on a uniform series of charts prepared by the American Geographical Society (the body responsible for the preparation and publication of the *Atlas*), it is hoped to build up, over the years, a volume of data in which the separate distributions can be compared. The problem of the comparability of methods, although mentioned, has yet to be resolved.

The second paper is concerned with the vertical distribution of temperature in the upper 100 m of the eastern Sub-arctic Pacific and describes the processes involved in the development and decline of the seasonal thermocline. This is followed by three papers which directly relate the distribution of physical and chemical properties to biological distribution; they deal with attached algae of the North-east Pacific and zooplankton species in the North Atlantic. One of these papers includes a plea for more taxonomic investigations. It is certainly a feature of the literature that whenever wide-scale distributional investigations are undertaken, many systematic problems have to be cleared up first.

Another paper shows how a knowledge of the life-history of a species increases its value as an indicator of water movements. It might well be added that to understand fully the distribution of a species, a knowledge of its life-history is essential. Such points emphasize the theme of *Marine Distributions*—that the distribution of plants and animals cannot be examined in isolation. The final paper is concerned with osmoregulation in some of the larger Crustacea, which the author groups according to their capacity to adjust to variations in salinity. This paper, based on experimental work, is refreshingly different from the three previous ones and demonstrates the use of physiological methods in distributional investigations.

The book ends with comments and a summary by Dr. L. A. Walford, without which it would lose a great deal of its value. He links the papers together and raises many of the problems involved in the investigation of the sea as an environment. Although the difficulties he lists are numerous the result is not wholly depressing, as he also suggests ways in which some of them may, at least partially, be overcome. He believes that one approach lies in the "... systematic mapping of all the many elements of the marine environment—currents, bathymetry, bottom sediments, salinity and temperature fields and distributions of all species of plants and animals", which is the plan of the *Serial Atlas*. Put this way, one may be excused, perhaps, for thinking that this is rather a tall order.

Some comment is necessary on the layout of the papers. Whether, in a publication of this type, abstracts at the heads of the papers are necessary or not, at least a consistent pattern should be followed. Four of these papers have neither abstract nor summary, one has an abstract only and one provides both an abstract and a summary. Some of the figures could be much clearer and it is unfortunate that, in the paper on temperature–salinity–plankton diagrams, Figs. 10*b* and 11*b* have been transposed in printing, particularly as it makes the necessary simultaneous comparison of two of the diagrams and their corresponding charts impossible.

Ultimately the success of this book depends on whether it directs attention to relationships between papers that would be overlooked if they were read separately, possibly over a long period. To those readers already familiar with the subjects discussed such relationships will probably already be apparent, but to those whose investigations at present appear to have less obvious connexions with these problems this book will be of considerable use.

A. de C. Baker

EDUCATION AND INDUSTRY*

By S. P. CHAMBERS, C.B., C.I.E.

Chairman, Imperial Chemical Industries, Ltd.

A SUBJECT such as I have chosen may conjure up the prospect of a disquisition on the balance which should be held between 'pure education' in the academic or philosophical sense, and vocational training, but this is not the case here. It is to quite a different aspect of education to which I wish to direct your attention. This aspect is concerned with neither the academic content of education nor with vocational training, but is concerned with the extent to which education in its broadest sense fits men and women for responsibility and control in industry. It may be that what goes wrong in the education which some people get is as wrong for vocations in other walks of life as for those in industry; but it is for other people to judge in these other fields.

In an organization as large and complicated as mine (Imperial Chemical Industries, Ltd.), there is need for men of many kinds with widely different training and different aptitudes, but, except for quite low-level routine workers, certain characteristics are needed in all of them. Briefly these characteristics are the capacity: (*a*) to weigh up factors and to come to firm decisions; (*b*) to control other men fairly and firmly and win their confidence; (*c*) to delegate responsibility and to tolerate errors of judgment in subordinates within reason and without inquests; (*d*) to take firm action, however unpleasant, where the standard of performance has fallen below the tolerable limit.

Even where the work does not involve the direct control of other men, there is usually the indirect and intangible control which is exercised when passing judgment on the work, character or capacity of other men.

These characteristics are needed right through from the charge-hand directly controlling the work of a few other men to the highest executives dealing with long-term policy. What is more important is that one or more of the essential characteristics can be absent from somebody who has been appointed—wrongly appointed—to quite a senior post and yet be present in a man who is doing a subordinate job really well but whose aptitude and training do not fit him for a more responsible post.

I believe that having these characteristics is basically a matter of education in its fullest sense and is neither an inherent quality nor a matter of vocational training; but there is no clear pattern from which we can determine the likely source of the 'haves' and the 'have-nots'. Some top-rank public schools and university colleges produce men of brilliant academic achievement who have poor judgment, no power of decision and no capacity to delegate work or to control men. These men can be the tragedies of industry because their deficiencies are not revealed in their academic record and are difficult to detect at a selection interview. They can get started on a promising career, but end in the wilderness of the unpromotable clever boys. On the other hand, the same schools and colleges can produce second-rate graduates who are first-rate men with all the characteristics I have listed.

The history of British industry during the nineteenth century and up to the outbreak of the Second World War teems with examples of men who have not had any formal education but who have had all the necessary characteristics and have become notable industrial leaders. With the growing complexities of modern large-scale industry with its scientific basis, the 'self-made man' with little or no formal education is vanishing. Yet some of the highest places in industry have been filled successfully by men whose education has been obtained the hard way. In these cases, the task of getting education and training the hard way has imposed personal disciplines which have probably led imperceptibly to the acquisition of those characteristics needed in industry. Sometimes, however, such a course produces an almost characterless 'swot'.

As I see it, the educational system of Great Britain produces from the point of view of industry good and bad candidates on a 'hit-or-miss' basis which is most unscientific. I have said that academic achievement is no guarantee that the other attributes of a good industrialist will also be present, but undoubtedly the ideal is a combination of academic brilliance and these other qualities.

From what I have said so far it will rightly be concluded that I am concerned here neither with academic education nor with vocational training, but with the development of character. I do not mean, and I want to emphasize this, the development of moral standards. All aspects of education are important—the acquisition of knowledge; the development of the power of thinking and reasoning; specialized vocational training, whether the vocation is to be that of a doctor, an engineer or an electrician; the inculcation of moral values; and, finally, the development of all those elements of character which enable a man to work effectively and harmoniously with his fellow workers. There are, of course, many other aspects of education such as the development of the power of appreciation in cultural matters so that in leisure time there can be full enjoyment in the fields of art, literature, music and so on; but I am not concerned with these here.

I have given a list of the characteristics which are needed for those in industry who are not engaged solely on routine work. I want now to explain the importance of these characteristics in a world in which large sections of industry are becoming more mechanized, more complex, and controlled in units which continue to grow in size.

First, a word about size. Economists in general like to see the maximum amount of competition as a spur to efficient and economic production, and I am sure that, in general, they are right. But the economic unit in many sections of industry grows with technological progress. For example, and I take an example from the chemical industry because I am on familiar ground, a plant to produce 20,000 tons a year of ammonia would have been regarded only a few years ago as large; to-day we are erecting two plants each to make 300,000 tons in a single stream of gas, and these, with one other plant, will supply the whole of the present requirements of the country. Moreover, the gases produced pass unseen through a series of plants from the raw material (naphtha) to a plant making concentrated mixed fertilizer which is fed straight into polythene bags for delivery to farmers and stockists. It is inevitable that all these plants, costing millions of pounds, should be under the same ownership. The economics of joint production are such that a whole range of other plants must be in the same ownership if there is to be economic production. Indeed, it is the spur of international competition which makes units in this type of production in Britain reach, for Britain, monopoly size. This is only one example of what is happening in many parts of industry, although, of course, there will always be some parts of industry in which production and ownership will be in quite small units.

---

* Substance of the Chuter Ede Lecture delivered before the National Union of Teachers on June 2.

In any really large undertaking the decisions which have to be taken can be classified. There are some decisions of policy which are of wider application throughout the whole organization and also of long-term significance; these clearly must be made at the highest level. Others are important but are more limited either in their effect on the organization as a whole or in the area of application. Decisions at lower levels must, of course, conform to the general policy. Too often there is a lack of co-ordination because the general policy in an organization has not been adequately communicated, and this, in turn, may be due to a failure to define and decide such a policy.

At each level in Imperial Chemical Industries, Ltd., there has to be the exercise of judgment on the relative facts, decision, and the communication of decision to lower levels of management. This is true of the main board of directors, to the chairmen of divisions, factory managers, plant managers and foremen, with similar lines of communications horizontally to those engaged on research and commercial operations. Very difficult questions of organization arise, and if these are settled badly, friction, frustration and bad management will follow. For example, the co-ordination of the functions of production and marketing has generally to be done below that of a Division Board level. If they are co-ordinated at a higher level, which used to be the case, relatively low level executive decisions involving several different functions would have to be referred to unnecessarily high level committees, the members of which are almost certainly less competent to make the decisions than men at a lower level because their contact with the material factors is more remote. If you only have the co-ordination of these functions at a high level anything involving a number of functions has got to go to the highest level, therefore co-ordination must be at a lower level. This is important. The 'man on the spot', if in fact the organization is bad and decisions go to a high level, then tends to despise those who have authority over him and then to distrust their judgment not only in those matters which could and should have been settled locally but also in matters which are proper to these men at higher levels of management—matters in which their judgment is likely to be superior.

The need to keep decisions down to the level where they belong is essential to the proper organization of a large business. There must also be the recognition that human beings, to whom powers of decision have been delegated, are fallible and that mistakes will be made. When mistakes are made, there is a natural temptation to bring the relevant decisions up to a higher level or to issue detailed instructions which, in practice, has the same effect. This temptation has to be resisted. In a large industrial organization the power to decide quite important matters must be delegated, and when there is doubt about the exercise of this delegated power, a firm self-discipline is needed at the higher level to resist the temptation to withdraw the delegated power. Where the record over a period of years reveals incompetence, then changes in personnel may be needed, but this is a different matter.

The capacity to delegate and not to get flustered if things go wrong at a lower level depends on the recognition at a higher level that mistakes will be made and that there must be no recrimination or the withdrawal of the power to delegate. The system of delegated power must be adhered to firmly and must be understood throughout the organization.

Only in this way can a large organization function effectively in conditions which are changing and which require the exercise of judgment and discretion at different levels without seeking detailed instructions from above. Ideally there should be communication of policy and of higher decisions to lower levels of management and no instructions on how the lower levels of management should carry out the policy communicated to them. In practice some instructions are needed, and care has to be taken on occasion to see that a decision to be taken at a lower level does not conflict with an important decision of policy, but such instructions should be kept to a minimum.

The alternative to this system of delegation and reliance on the judgment and capability of other people is a vast bureaucratic machine in which there is the fiction that, assisted by expert advisers, the top management is omniscient and capable of issuing detailed instructions on everything that has to be done. All initiative is taken away from lower levels of management for whom deviation from detailed instructions is an offence, to be put on the record. Such a system is productive of a vast amount of paper, and is grossly inefficient, slow and inflexible. Some Government departments are suspiciously like this; but they need not be.

There are at least two major objections to detailed control from the top. The first is inflexibility and slowness to cope with changed or changing conditions. The one which comes to my mind (this is a little controversial but it is a simple example) is the case where planning approval is required to put up a building, and where the local authority, the county authority and a central Government Ministry all have powers entitling them to go into every detail and to exercise a power of veto. Our multi-layer system of Government is, I am sure, right as a matter of democratic principle, but extraordinarily inefficient in practice because no attempt seems to have been made to introduce into it any principle of management by delegation which can cope with changing conditions.

The second objection is that a bureaucratic system fails to take into account the great need of intelligent men to express themselves by the exercise of their individual judgment and in so doing to act as free men doing effective work instead of being the cogs in a machine driven only by the centralized force of decision at the top. For men of intelligence to know that they are the slaves of detailed decisions by men who have been put in authority over them, but who have neither the knowledge nor the time to make these decisions well, there is a sense of frustration and humiliation which communicates itself still further down the line.

In a simple and static society faults of organization or management are relatively unimportant; they get ironed out by experience; in a modern and progressive society they can lead not only to disorder and other difficulties of management, but they can lead ultimately to decadence. The need for men to be able to express themselves and to use their mental and moral powers in their work is as important as the need to maintain high material standards of living and the environment for intellectual enjoyment during the extended hours of leisure.

It is here that I come back to education. How often have I met men of unblemished character, of high academic achievement, but whose life, sheltered from the harsh need to make important decisions, has left them timid and irresolute, or stubborn because of the fear of making a mistake. Life at a university with its intellectual and inconclusive discussions at the postgraduate level is, on the whole, a bad training for the real world and only men of very strong character surmount this handicap. Training in the principles of management at a later stage will not convert a timid man into a man of decision. Who along the educational chain is watching this failure of character development in men who may be getting high praise for their academic achievements ?

In some men of high intellectual ability, there is a failure of another kind. Concentration and success in a narrow field, which for my subject is likely to be scientific, can lead to an arrogance which reveals itself in a contempt for the problems in other and broader fields. The pure scientist who is infected in this way, and only a few of them are, will regard applied work as needing only a lower standard of intelligence, but he will not say so. He will also regard the problems of management and of working harmoniously in a heterogeneous team as non-existent or just simple matters to be dealt with *ad hoc* by anybody with average intelligence. He will not understand that that combination of powers of intellect and judgment which is needed for applied scientific work by brilliant scientists struggling with a specific objective is something which he probably does not possess; nor will he understand how much harder is the task of working successfully in a team of men than the indulgence of intellectual skill on abstract theorems.

I have met men of this kind who are contemptuous of economists because they have been deceived by the day-to-day environment and data which are subjects of economic study; they have failed to observe that the tasks of economic analysis are in some ways more difficult and more baffling than, say, those of nuclear physics because so much of the material is both familiar and immeasurable. The fact that we have made less progress with the former than with the latter is perhaps some evidence of this.

One of the reasons for our failure to produce enough men of high academic standards who have also the developed characteristics to cope with the hard problems of real life may be that our university education is almost wholly in the hands of academic people who have not these characteristics themselves. I have too often attended meetings chaired by dons who have been pathetically indecisive and have allowed discussion to drag on and to wander in the most undisciplined manner into wholly irrelevant by-paths.

Perhaps the changes envisaged in our system of higher education may lead to improvement; but I feel that this aspect of character development requires more positive attention. There is no doubt that organized competitive sport, particularly where teams are involved, makes an important contribution to some aspects of character training; but sport is confined to the physical world and we need its equivalent in the intellectual world.

So far I have been dealing with higher education and have had in mind the filling of higher posts in industry. The problem exists also at the earlier stages of education and is no less important here.

I am treading on delicate and, for me, less familiar ground when I say that, for what seems to me to be a growing proportion of teenagers, there appears to be a loss of a sense of purpose. If the proportion is smaller than I fear, and others are better able to judge than I am, so much the better; but the evidence so far as I can see spreads across teenagers from many walks of life and is not confined to those from under-privileged families.

Nobody would wish to return to the harsh disciplines of the nineteenth century; but the decline of the influence of Christian churches seems to have left a vacuum, and has left too many people rudderless. Those who have reached university-levels of education have generally applied to themselves their own disciplines and have achieved their own sense of purpose, but others receive formal education at school but apparently little leadership or direction. Outside influences seem to me to be generally degrading rather than inspiring. We may all disagree with Karl Marx when he said that religion was the opiate of the people, but would he have given this same description to the great quantity of sensuous and sentimental rubbish poured by pop-singers into the ears of teenagers every day? Listening to this outpouring from the radio or television requires no mental effort and is a form of dope, which for its time-wasting alone must do damage at an age when there is the maximum amount of mental and physical energy available. Perhaps it is this dope, coupled with an absence of any impelling self-discipline, which produces a listlessness and a lack of enthusiasm for anything outside this world of sentimental fantasy; I do not know: I wish I did.

Work in industry which is done in a perfunctory manner by people with no enthusiasm and no sense of purpose is nearly always bad work; for those who are needed for leadership at the level of charge-hand, foreman, supervisor, or higher posts, it can have a bad and widespread influence. Nobody who lacks enthusiasm can inculcate it in others, and the great need in industry, particularly in large-scale industry, is enthusiasm at all levels.

It is in this matter of a sense of purpose that I have been struck and rather worried by what I have seen in the U.S.S.R., from which I have recently returned. My observations, both in Britain and the U.S.S.R., are too few and too accidental to be reliable, but there appears to be a great difference in this matter of inculcating a sense of purpose and enthusiasm. The difference goes right back to training at the pre-kindergarten stage in the crèches provided for the babies of mothers working in factories or offices. My mind rebels against what I saw, and I would hate to see its equivalent in Britain; but it revealed, in my judgment, a vacuum in our own system which I feel must somehow be filled.

After the crèche stage (four months to three years of age), and I visited these, there are in the Soviet Union kindergarten schools for children from three to six years of age whose parents are working and who cannot conveniently be looked after at home because of the absence of a grandmother. Many of these are boarding kindergartens which the parents visit only on Sundays. As most married women work, there are many such kindergartens. My wife visited one of these boarding kindergartens and listened to some good singing by three-year olds. The songs were all in praise of Lenin, of Communism, of the U.S.S.R., or of the cosmonauts of the U.S.S.R. At another school which I visited some time ago in another country in Eastern Europe I saw the same thing—the teaching to the very young of little songs in praise of Lenin and of the principles of Communism. From then onwards education and indoctrination go together at all levels. I went into classes at higher levels and found what, in my judgment, were good standards of teaching and a down-to-earth relationship of this teaching to the needs of everyday life. The teaching of chemistry as a general subject to all pupils was excellent and taken further than in British schools; it was related to the chemical industry and, as in other subjects, there was always the background of the needs and purposes of the community as a whole. Special facilities for children and teenagers to follow their own inclinations in music, art, literature, and so on, were provided in the 'Palaces of Pioneers', for which the only qualifications were good work and conduct at school.

In the U.S.S.R. I am sure that loyalty to Communism is firmly built into the minds of everybody less than forty-five years of age, and that this is attributable to a large degree to this indoctrination from the earliest years. A parallel can be seen in the teaching of Christianity in small children's hymns; and the indoctrination in the U.S.S.R. to-day seems comparable to that of the Christian church in Europe, particularly prior to the time of the Reformation when deviation in belief was heresy.

I am repelled by this use of the educational system for the purpose of indoctrination along a single path from which deviation in act, if not in thought, is a grievous sin. On the other hand, it is impossible to spend any considerable amount of time in the company of men, women and children in the U.S.S.R. without observing that, to all appearances, they have, and work with, a sense of purpose. Having thrown off one form of indoctrination through education, without accepting any other, I am left wondering whether, for certain age-groups, there is left in Britain any sufficient sense of purpose or of social responsibility and, in particular, whether there is that training of character which is needed not only in social or intellectual fields but also in the vital work of industry. Absence of a sense of purpose may not be so widespread as I fear; many people are in a better position to judge than I am, but if the problem is a growing one it will need deep study and that free public discussion which is possible in Britain to-day and which can alone lead to the development of solutions.

In another way, and one which is very relevant to the efficient operation of the economy, there has been a marked change in the U.S.S.R. Under Stalin the centralization not only of long-term plans but also of much detail was accompanied by ruthless action if the performance of individuals fell badly short of requirements, particularly if this might be attributed to disaffection or even disloyalty. There was no doubt a control by a form of terrorism. Fear of making decisions, even relatively unimportant ones if these involved risks of making mistakes, coupled with the belief that a gigantic central plan could control the whole economy in detail, led to decisions by committees at all levels. The result was delay and a good deal of muddle and inefficiency. Decisions which should have been taken at lower levels were taken at higher levels—sometimes at very high levels—with added strains on the occupants of higher posts.

Since Stalin's death there has been far less recrimination and the abandonment of terrorism as a method of enforcing conformity. Decentralization and delegation of authority are the order of the day, and individuals are encouraged to take responsibility. Stalinism has left a legacy which has not yet been wholly eradicated. The exercise of the power of decision by individuals at high levels is noticeable. I saw a good deal of it, but at lower levels there appears to me to be still far too much committee work, and too much passing down of detailed instructions. The paper work for quite simple matters seems altogether excessive. Moreover, when men have passed much of their earlier working lives working on committees on the basis of detailed instruction from above, it is not easy to change to a system which requires initiative, judgment and the power to take decisions. Indeed, it may be some time before all down the line there are sufficient men who can take responsibility on their own shoulders, and the need for committees and detailed instructions may remain for some considerable time yet. There is no doubt, however, that the policy and the trend are in this direction.

Perhaps it is a coincidence but there appears to be to-day less rigidity in the U.S.S.R. in matters of doctrine. Home ownership through the co-operative purchase of flats is encouraged, and is spreading. The desire to own a flat and to have furniture that is different is accompanied by a desire to have better and different clothes. All these seem to me to be indications of a desire for self-expression by individuals who are rediscovering the joys of individuality as well as those of community. They may have a long way to go. Perhaps we, in our educational system, also have some way to go to rediscover how to inculcate a sense of purpose in those who seem to lack it, and how to train men and women with the character needed to shoulder the burdens of a world of growing complexity.

INCIDENCE AND POSSIBLE SIGNIFICANCE OF INHALED OR INGESTED POLONIUM

By Sir ERNEST MARSDEN, C.M.G., C.B.E., F.R.S.

Formerly Member of New Zealand Council of Nuclear Science

RECENT papers by Hill, Osborne and Mayneord[1] of the Physics Laboratories of the Institute of Cancer Research, by Radford and Hunt[2] of the Harvard School of Public Health and by Marsden and Collins[3] of the Dominion Physical Laboratory, New Zealand, have indicated the extent and possible human importance of naturally occurring polonium-210. In this article I shall record some further experimental evidence of polonium and its possible effects in cancer initiation at various sites, including the lung, and also in relation to certain possible induced genetic changes.

Polonium-210 RaF is an α-particle-emitting nuclide of half-life 138 days. The amount present is normally controlled by its parent once removed, RaD or lead-210 of 22 years half-life. The intermediate product RaE has a half-life of 5 days and emits soft β-rays. It is considered that α-particles can initiate protein molecular changes to an extent far greater than the proportionate ionization they produce compared with β-rays and γ- or X-rays.

Polonium can enter the body either through the water consumed, or as a contaminant of the air inspired, or as a trace constituent of foodstuffs via radioactive soil or from natural fall-out as the result of disintegration of radon which has escaped into the atmosphere from soil. In the case of drinking-water, the amount does not appear to be relatively important except for certain artesian waters generally also highly charged with radon. Normal air is said to contain lead-210 to an average extent of 0·003 pc./kg with upwards of 0·09 of this quantity of polonium-210, according to season. This figure would correspond to some 0·007 pc. inhaled by an average person per day.

Two widespread probable sources of inspired polonium, however, are: (1) inhaled tobacco smoke, when certain tobaccos are used in the cigarette blend and in the absence of a suitable filter; (2) the exhaust of motor-car petrol engines when lead compounds are used for enhancement of octane rating. These two sources could assume varying relative importance in different conditions and regions, though too little is known regarding the magnitude of the latter. The average retention period in the lung of such inspired polonium is of the order of 70 days but will probably vary with particle size, the nuclide presumably being more readily removed before disintegration when not associated with certain types of particulate matter, for example, smoke condensate or car exhaust material under certain conditions or urban pollution.

Tobacco

The series of α-particle measurements reported in the paper by Marsden and Collins[3] and others have been extended with results confirming the wide variation, more than 30 : 1 in the activity of tobaccos grown on different soils, the highest about 15 pc./g raw leaf (wt. of leaf tobacco in one cigarette about 1 g). The tobaccos showing highest activity are those grown on soils of low *p*H such as are derived from radioactive older granites or granodiorites occurring in parts of Southern Rhodesia, North Queensland, and elsewhere. The α-activity of a large range of parent granite materials has been measured and will be reported separately. They vary in total α-activity from 150 pc./g to 5 pc./g, the granites with lowest activity being, in general, those with less potash or soda granites,

Pergamon Press Publications

Atlas and Tables for Emission Spectrographic Analysis of Rare Earth Elements

Charlotte Kerekes

Compiled for spectroscopists analysing rare earths with the Zeiss Q-24 spectrograph or with similar instruments. The Atlas makes it possible quickly to identify the most sensitive lines – the analysis lines – of the rare earths. The wavelength values of these, as well as the wavelengths and relative intensities of the interfering spectral lines belonging to other rare earth elements including Sc and Y, are also given.

High Temperatures in Aeronautics

Edited by **C.Ferrari**, Politecnico di Torino

Partial Contents:

Effetti delle alte temperature in aerodinamica – C.Ferrari; Theoretical and experimental investigation of supersonic combustion – A.Ferri, P.A.Libby and V.Zakkay; Moti linearizzati non in equilibrio di miscele bi-reagenti – L.G.Napolitano; Non-equilibrium flow through a nozzle – P.A. Blythe; Radiative transfer studies and opacity calculations for heated gases – S.S.Penner and R.W.Patch; Esperimenti di propulsione elettrica mediante motori elettrotermici – A.C.Robotti and M.Oggero.

International Series of Monographs in Aeronautics and Astronautics, Volume 15.

450 pages. £5 5s ($15.00)

Advances in Enzyme Regulation, Volume 2

Edited by **G. Weber**, Pharmacology Department, Indiana University School of Medicine, Indianapolis, Indiana

The proceedings of a symposium on Regulation of Enzyme Activity and Synthesis in Normal and Neoplastic Liver, held at Indiana University School of Medicine.

Partial Contents:

Regulation of enzymes involved in gluconeogenesis – G.Weber, R.L.Singhal, N.B.Stamm, E.Fisher and M.A. Mentendiek; Metabolic and hormonal regulation of phosphopyruvate synthesis – H.A.Lardy, D.O.Foster and P.D.Ray; A possible role for acetyl-CoA in the control of gluconeogenesis – M.F. Utter, D.B.Keech and M.C.Scrutton; Studies on the nature and specificity of the induction of several adaptive enzymes responsive to cortisol – F.Rosen and C.A.Nichol; The regulation of apoenzyme levels by coenzymes and hormones – O.Greengard; Substrate-type induction of tyrosine transaminase, illustrating a general adaptive mechanism in animals – W.E.Knox; Some aspects of the development, biology and biochemistry of rat hepatomas of different growth rate – H.P.Morris, H.M.Dyer, B.P.Wagner, H.Miyaji and M.Rechcigl; Correlation of enzyme activities and metabolic pathways with growth rate of hepatomas – G.Weber, M.C.Henry, S.R.Wagle and D.S.Wagle; Synthesis of purines and nucleic acids and catabolism of purines by rat liver and hepatomas – G.P.Wheeler, J.A.Alexander and H.P.Morris; Studies on thymidylate phosphatase, thymidine kinase and thymidylate kinase activities in some transplantable rat hepatomas – J. Bukovsky and J.S.Roth.

408 pages. 100s ($15.00)

Fluid Dynamics Transactions, Volume 1

Edited by **W.Fiszdon**

Partial Contents:

Exact numerical methods in the boundary layer theory – A.A.Dorodnitsyn; The effect of surface catalytic efficiency on stagnation point heat transfer – J.R. Busing; Hypersonic, plane couette flow in rarefied gas – J.Luboński; Les équations de transport des quantités moléculaires pareilles à l'entropie – M.Lunc; A method of calculating the flow in a divergent nozzle with oscillating walls – W.Fiszdon; Oscillations of a viscous liquid drop in a turbulent gas – J.Chomiak.

406 pages. 100s ($15.00)

Integration of Equations of Parabolic Type by the Method of Nets

V.K.Saul'ev

Partial Contents:

Absolutely unstable net equations; Asymmetric net equations; Method of mean arithmetic and multi-nodal symmetric method; Spherical and cylindrical regions; Equations of increased accuracy; Net equations with fictitious nodes; Non-uniform nets; Multi-step equations; Parabolic equations of higher than the second order; "One-dimensional" elliptic net equations; Methods using Chebyshev polynomials; Iterative methods of the second degree; Methods of block iteration.

International Series of Monographs in Pure and Applied Mathematics, Volume 54.

358 pages. 80s ($12.00)

Plutonium

M.Taube, Institute of Nuclear Research, Warsaw.

Contents:

Nuclear properties of plutonium; Chemical properties of plutonium; Physiological effects of plutonium and health physics; Plutonium technology; Plutonium nuclear fuel; Role of plutonium in development of nuclear power; Bibliography; Subject index.

264 pages. 60s ($8.50)

Optical Illusions

S.Tolansky, Department of Physics, Royal Holloway College, University of London.

Contents:

Illusion in nature; The effect of weak wings; Convergence – divergence; Some further illusions; Irradiation illusions; Crossed-bar illusions; The setting sun and moon illusions; The moon in art; Illusions produced by hatched lines; Illusions involving oscillation of attention; Illusions due to instrumentation.

168 pages. 35s ($5.00)

The Cube Made Interesting

A.Ehrenfeucht

Contents:

Preface; The cube as a member of a larger family of polyhedrons; The planes of symmetry and axes of symmetry of the cube; The group of rotations of the cube; Sections of the cube; Coloured blocks; Constructions from coloured blocks; Blocks that can be cut out of a cube; How a bigger cube can slide through a smaller one.

Popular lectures in mathematics, Volume 9.

92 pages. 21s ($3.75)

MICROMANIPULATORS

if you use a
MICROSCOPE
you need a
SINGER
FULLY PATENTED
MICROMANIPULATOR

Singer micromanipulators are used in most laboratories all over the world. Three types available:

Mk I Low power for magnifications ×1 to ×200

Mk II For magnifications ×1 to ×500

Mk III High power for magnifications ×100 to ×1,000 *plus*

The most advanced instruments for micromanipulation. As described by Barer and Saunders-Singer with further improvements.

Full details and demonstrations upon request to :

SINGER INSTRUMENT CO. LTD.,
Fountain Court, 83 London St.,
Reading, Berkshire, England.
Telephone: Reading 53613.

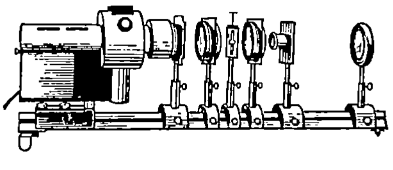
REVEALING THE EFFECTS OF
← STRESS →

IMPORTANT APPLICATIONS OF SPINDLER & HOYER OPTICAL BENCHES

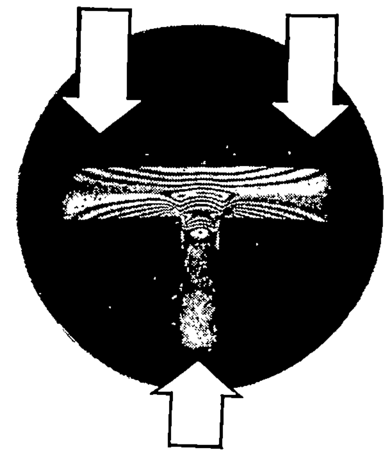


Beam of light from carbon arc lamp is gathered in optical condensers, transmitted through polarizing screen, specimen, analysing screen and objective, which projects it on viewing screen. Spindler & Hoyer optical benches feature an automatic feeding device to move carbons uniformly through the lamp and eliminate adjustment. A wide range of sliding carriages and other accessories makes them extremely versatile.

(2) TEACHING

When specimens of plastic or special glass are fitted to a Spindler & Hoyer optical bench and subjected to stress, an image showing the effects is projected for observation. It may be filmed or photographed as a record. The instrument provides lecturers with a particularly graphic means of illustrating the principles of mechanics at work.

Industrial applications are numerous—Spindler & Hoyer optical benches are valued as time and money-saving equipment in many leading laboratories.



For example, they are used to test glass and plastic mixes and product designs before manufacture, and to investigate the effects of stress on engineering projects at the technical design stage. For full details, please contact the sole U.K. distributors,

and this extends to soils derived therefrom. Many granites derive most of their activity from thorium; but there are many in which uranium predominates as a source. This question has relevance to the proportion of α-particle contribution from polonium, which is one of the uranium series. In equilibrium, and in the absence of leaching effects, polonium would contribute one-eighth of the total α-particles from the uranium series.

Tobacco plants were grown in a greenhouse at the New Zealand Tobacco Research Station, Motueka, in large pots, using low-activity soil as control; but in other pots artificially enriched with finely ground different radioactive uranium ores and also monazite. Overseas field conditions regarding high radioactivity could be simulated, both in regard to soil and tobacco activity, and studies made, for example, of distribution of activity in leaves at various levels in the plant so-called lugs, cutters and tips. Although monazite itself (from Bryon Bay, Queensland) was not readily taken up by the plant, yet in the case of other ores in which uranium and thorium contributed, the uptake of uranium and thorium measured by the occurrence of 'doubles' (thorium and thorium *A*) was in many cases about proportionate, that is, there was little evidence that mesothorium (Ra 228) was the only thorium family parent picked up by the plant. Further observations are in progress.

A reconnaissance experiment was made to throw light on the question of the probable contribution of polonium from natural fall-out absorbed by the surface of the leaves. Dried commercial tobacco leaves were taken and equivalent parts of the leaf were placed with: (*a*) the upper surface against a phosphor; (*b*) the lower surface; while in some cases the leaf was dried until brittle and the powdered material placed against a third phosphor surface and scintillation counts made. All the tobaccos were Virginia cigarette type. The thickness of the leaf is several times greater than the range of α-particles. Typical results are given in Table 1.

Table 1. α-COUNTS/H FROM 50 CM²

Country of origin	Upper side of leaf	Lower side of leaf	Approx. percentage from thorium family
South Africa	12	5	30
New Zealand	9	8	35
S. Rhodesia	91	95	50
Thailand	21	20	50
U.S.A. (Eastern)	18	16	30

In general the lower side appeared to show a slightly higher proportion of thorium, but numbers are too small for statistical significance. It would be interesting to know in which locality the particular South African sample was grown.

The foregoing tests were carried out on board ship and weighing facilities were not available to give moisture content, which would affect α-particle absorption of the powdered sample, so the activity of the powdered leaf is not given, but it differed little from the mean values in Table 1. It is concluded that in spite of possible effect of surface waxes and small estimated amounts of soil dust on the surfaces of the leaf, there is probably some small effect of polonium fall-out; but in the case of higher activity tobaccos it is only a minor factor compared with activity derived from soil through the roots.

The foregoing figures are not to be taken as representing averages from the countries concerned as there is a large variation within each country, particularly Southern Rhodesia and Australia.

A large number of samples have been measured from tobacco leaf imported from various countries into New Zealand, and made available by co-operating commercial concerns, but if we are to attempt to give reliable representative figures, systematic sampling would be necessary, also selection of leaves from various soil types and positions on the plant from which the leaves are taken, also the soil moisture and climate conditions of the particular year of crop growth. For example, the New Zealand figure quoted is an average from soils derived mainly from 'Separation Point', low potassium granite, but with an admixture of so-called Motueka gravel soil of New Zealand greywacke origin. The purely granite soils over a larger part of the growing area gave an α-activity of 5 pc./g and the background γ-radiation was 0·0060 mrad/h, while only a mile away over the soils on which the sample referred to in Table 1 was grown the radiation was 0·010 mrad/h. The α-activity of soils and tobacco was found to show correspondence. There is also a probable influence of variety or genetic strain as in the case of wheat referred to in previous papers, although it is not so evident when using Virginia type cigarette tobacco only. There is apparently a preponderance of 'Hicks' variety grown in Southern Rhodesia, a proportion of 'Burley' in the United States and a type called 'Virginia Gold' in New Zealand, each bred and grown with regard to yield, quality and local disease resistance. Samples of the three varieties were grown on the same Motueka soil in New Zealand, and the specific activities were measured and found to show little difference.

Polonium in Motor-car Exhaust

It has long been known that lead processed from most of its ores contains considerable lead-210 and consequently polonium. Such lead was avoided for construction of electroscopes, etc., in the early days of radioactive measurements. It is natural, therefore, to suspect that lead in the anti-knock agent, of petrol lead tetraethyl, might contribute polonium to the combustion exhaust gases. Polonium salts are volatile, the chloride, for example, at 200° C only. A test was made of lead from lead tetraethyl solution as used commercially, and there was considerable α-activity when the material was treated with fuming nitric acid before precipitation to remove organic components. In a normal method of precipitation the polonium remained in the organic portion and the precipitated lead was at first inactive by α-particle measurement, but grew in activity in the following months, showing that polonium was involved.

Two sheets of lead of differing origin, of age possibly 10–15 years, were taken from the workshop and were given a fresh clean machined surface. The α-activity was in each case approximately 180 particles/100 cm²/h. A similar piece of lead, age known to be of the order of 120 years, supplied to me by Harry L. Dowsett of Dowsett Engineering Co., gave an activity of only 4 particles per 100 cm²/h. These figures correspond roughly with the decay of lead-210 of period 22 years.

By courtesy of Shell Co. of New Zealand, scrapings were obtained of the inside of the exhaust pipe of the C.F.R. engine used for testing leaded fuels. The pipe was an old one taken out of service four months earlier and had been surrounded by water-cooling pipes. The scrapings were measured for α-particles and displayed considerable activity, corresponding when corrected for lead content, roughly 16 per cent, to that of the lead tetraethyl used. Another test was made of the scrapings from the inside of the exhaust pipe adjacent to the engine of a new motor-car. The car had been in use for one month only using leaded petrol. The α-activity was pronounced and has grown roughly 10 per cent in the four weeks which have elapsed since the sample was taken, indicating that much of the original polonium may have escaped into the air, being more volatile than the lead which was more readily deposited. To test whether the anti-knock properties might be due to the initiating action of α-particle produced ionization or radicals, the Dominion Laboratory kindly prepared samples of lead tetraethyl from the two samples of lead referred to already. The lead tetraethyl produced had good anti-knock properties in both cases, some 80 per cent that of material supplied commercially but with the old lead possibly slightly less effective. However, these tests need repeating in a few months' time when polonium may have grown, but they did show that lead tetraethyl, prepared from old lead or from inactive ore, such as certain samples of galena which were also tested, can be used for octane enhancement without giving polonium to the car exhaust gases. It should be possible to design an exhaust pipe system which will condense out the lead itself should this be considered desirable for other reasons. The average amount used appears to be of the order of 2–3 g lead per gallon of petrol.

It may now be speculated generally and briefly on the possible significance of inhaled or ingested polonium neglecting the effects of other more fugitive α-radiating nuclides and also free radicals in the smoke condensate, as discussed in the paper by Marsden and Collins[3]. It is apparent that unlike radium and strontium-90, which accompany calcium to bone sites, polonium moves more to the soft tissue, and Osborne has reported quantities in the lung and reproductive organs. The destructive power of its α-particles is well illustrated in a photograph following the article by Radford and Hunt[2], already referred to. A man inhaling the smoke of 25 average British cigarettes a day probably deposits on his lungs and trachea some 8 pc./day of polonium, whereas the total dietary intake of radium is only about 2 pc./day excluding daughter products, and the latter is more subject to excretion or transfer to less hazardous body sites. In passing, however, mention may be made of the possible ingestion of polonium when a certain popular breakfast food is used. One sample of such gave an activity of 1·2 pc./g of which possibly 1/12 was polonium. If 2 oz. of this were consumed each day, the corresponding dietary intake would be 5 pc. Formerly the use of such active wheat was not considered a possible hazard because of the amount of dilution of its radium with the relatively large amount of inactive calcium in milk normally consumed with it, but when we consider polonium the position could be different.

To revert to cigarette smoking, as is well known there has been a striking increase in rates of diagnosed death from lung cancer during the past 50 years, that is, some 40 times in certain age groups in Great Britain. If we superimpose on the curve of increase among adult males since 1916 and, using a suitable scale factor, points representing the figures of imports of Southern Rhodesian tobacco, we obtain a startling correspondence, with a lag of 10 years in cancer figures corresponding to latent development period and delay in manufacture. However, such a correspondence may be largely fortuitous and diagnosis has improved, and possibly one could obtain much the same degree of correlation with figures relating to use of certain leaded petrols, or even, as a friend facetiously pointed out, of radio licence numbers, though not over the whole period to 1963.

The death rates of males from lung cancer for South Africa or New Zealand, Australia, United States and Great Britain are very roughly in the ratio of 22 : 30 : 39 : c. 60. These show a very general relationship to the amount of polonium activity inhaled from cigarettes consumed possibly if we include a factor in the United States and Great Britain for the possible effect of lead from petrol. The South African tobacco seems to be low in activity, though only two samples have been measured. As to Southern Rhodesia, I am informed that the male lung cancer death rate is the same as the figure quoted for South Africa and New Zealand, but am uncertain regarding age grouping. In New Zealand the deaths from lung cancer have followed the general world upward trend until 1956, when the curve abruptly levelled off significantly for 5 years. This may correspond to very considerably increased use of local tobacco, less radioactive than imported leaf or manufactured cigarettes. However, during 1957–61 considerable Rhodesian tobacco was imported, some 6 per cent of total, and it may be interesting to note that the male lung cancer incidence in 1962 and 1963 has again shown an increase, probably significant. The crude male deaths from lung cancer during the years 1957–63 were 357, 338, 363, 342, 395, 438 and 461 respectively. Australia has recently used some 25 per cent of its large consumption of cigarette tobacco from Rhodesia, plus that from North Queensland, both high activity tobaccos. The American figures are higher than Australian although tobacco activity is much the same, but considerably lower than those of Great Britain, as is the average activity of its cigarette tobacco correspondingly. Great Britain now imports some 30 per cent of its tobacco from Southern Rhodesia and Nyasaland and the activity of its cigarette blends was found, from examination of old cigarettes back to 1914, to have increased with the years and also the number of cigarettes smoked per head has increased in all countries. In studying correlations the difficulty is (*a*) latent period, (*b*) proportion of activity due to polonium. It may well be that the generally assumed latent period, that is, 20 years, is too high.

Mention may be made of the evidence derived by G. Dean[4] and D. F. Eastcott[5], who found higher lung cancer rates among migrants from Britain to New Zealand, South Africa and Australia compared with white local population. This may possibly be explained in part by the higher radioactivity of average British cigarettes. The correspondences quoted here, however, do not constitute proof of causation; but they arouse suspicion and are indicative of directions for further investigations and for remedial actions. It is probable that even if polonium is not absorbed directly by plant roots from the soil, since its compounds tend to have colloidal properties, yet lead-210 is freely transported. Thus within two years of gathering, which is less than the time normally allowed for fermentation, maturation, manufacture and retailing, polonium will have reached practical equilibrium, that is, within 3 per cent with such lead-210. It is not known whether lead is selectively taken up from soil compared with, say, radium. This may well be so under certain acid soil conditions. Some early results obtained by me point in this direction[3].

The possible case against lead anti-knock compounds, etc., needs much more investigation than that recorded in this article. The lead-210 in lead ores and compounds varies considerably with different origins and possible use of older reclaimed lead in processing. Some, probably secondary, ores have been examined which show little activity.

It is not improbable that some lead octane agents may contain polonium up to 10 pc./g. If 3 g per gallon are used this would correspond to 30 pc./gallon. Roughly converting this to content per litre of exhaust gases and assuming a man operates for 8 h/day in such exhaust, say, 100 times air diluted, one may deduce that such a person inhales of the order of 0·12 pc./day. This is small compared with that of the average cigarette smoke inhaler in Britain but may be more comparable in some other countries, as indeed might be inferred from the investigations of Poche *et al.*[6] in Germany. Tests of two samples of German tobacco leaf gave values 0·4 of the average used in the United Kingdom—a sample of Russian similarly—but considerations arise as to particle size and sites of deposition in the two cases. However, the figures, although an order of magnitude greater than under natural conditions, are too uncertain for further speculation, and experimental data are required relating not only to sources of lead components, but also of the actual content of the car exhaust gases under various conditions of car operation, that is, 'idling'. It would also be well to investigate the free radicals present and the lower aliphatics which might be the source of carcinogens in conditions of incomplete combustion.

Further mention must be made of possible effects of ingested polonium from diet. In a previous paper[7], the case of a group of Niueans was discussed and now further biological chromosomal tests are in progress, also an examination of food polonium-status. Apart from the very special case of certain Niueans, the Polynesians generally, including the Maoris, have a considerably greater intake of polonium-210 than Europeans, because of the large amount of sea shellfish they consume many times that of Europeans. The plankton food of such shellfish contains large amounts of polonium. I have made measurements in many ocean areas. The activity is very high and of the order of 12 pc./g plankton, dried at 120° C, and is predominantly polonium. It may possibly be significant that the Maoris have a large incidence of stomach cancers and also, to take one genetic impairment only, a 6-fold greater incidence of club foot[7,8]. This ratio, which has been recently investigated and confirmed by Dr. Peter W. Tapsell of Rotorua (private communication), does not appear to me to be wholly explainable by consanguinous marriages.

An examination of the figures of incidence of cancers of the digestive track in New Zealand in different regions lends support to the idea of a relation to soil and foodstuff radioactivity. Regional figures were supplied to me by N. H. Taylor (lately director of the Soil Bureau, and with whom I have discussed soil trace element questions during many years), and these are significant, but will be converted to a soil type basis. In particular an area in which the soil is of low activity, largely because of derivation from low-activity granite and rocks, gives an incidence of cancer of the digestive track only 40 per cent of that of a neighbouring area in which the soils are derived from highly active Karamea Granite and from greywacke. The relative figures indicate that investigation is worth while since remedial action is likely to be simple. There are, of course, other factors, such as rainfall.

In conclusion, it is appreciated that the various questions raised are perhaps somewhat hypothetical and naturally controversial. The importance of the subject justifies us in exploring such considerations as are advanced, since if causal connexions can be established the matter would assume wider social and political implications. The directions of these need not be enumerated at this stage.

I thank the director (W. H. Ward) and staff of the Dominion Physical Laboratory for facilities and advice, the Wellington Branch of the British Empire Cancer Campaign for a small grant, the New Zealand Tobacco Research Station, in particular Mr. D. S. C. Wright, for undertaking laborious experiments, New Zealand Tobacco Companies, Ltd., for assistance, and the Shell Co. of New Zealand and the United Kingdom, and Dominion Laboratory for ready help in work on leaded compounds used in petrol.

THE ANTI-LOCUST RESEARCH CENTRE, LONDON

By Dr. P. T. HASKELL

Director

In order to provide increased facilities for research the Anti-Locust Research Centre, one of the scientific units of the Department of Technical Co-operation, has recently moved to new accommodation in College House, Wrights Lane, Kensington. The new Centre was officially opened on April 28 by the Right Hon. Robert Carr, Secretary for Technical Co-operation. The opening ceremony was attended by representatives of many of the international organizations with which the Centre collaborates, such as the Food and Agriculture Organization of the United Nations, the World Meteorological Organization and the international locust control organizations, by representatives of Embassies and High Commissions of countries which the Centre assists or with which it co-operates in locust research and control; and by scientists and others who are specially interested in the work of the Centre.

At College House all sections of the Centre except the Taxonomic Section, which for obvious reasons remains in the British Museum (Natural History), are together under one roof for the first time. This has meant bringing in the Insecticide Section, previously attached to the Chemical Defence Experimental Establishment at Porton Down, and the Behaviour Unit, previously working in the Hope Department of Entomology at Oxford. Despite these additions, it has been possible in the new building to extend the space and increase the facilities of all sections.

In the laboratory, there are specially designed constant-temperature rooms for locust breeding and experimental work, including a cold room; all rooms in the central section are air-conditioned. Special planning was necessary in the Insecticide Section to prevent the toxic chemicals used therein affecting biological work, and this section has a separate air-conditioning and filtering plant. There are biological, physiological, biochemical and behaviour laboratories, and special facilities include an interference microscope and counter-current, chromatographic, electrophoresis and electro-physiological apparatus. There are two wind tunnels, one for studying locust flight and the application of insecticides to flying locusts and the other a special insecticide spraying tunnel. Because of the allergy to which locusts give rise, and to which some people are extremely sensitive, the laboratories and locust breeding rooms can only be entered through changing-rooms in order to minimize the transference of the allergens to other parts of the building (Fig. 1). Cartographical and biogeographical research facilities include the provision of new map rooms, archive and data-storage rooms and modern map filing and display facilities. Accommodation is also now provided for the recently formed Field Research Section, which was established to meet added overseas requirements when the Centre became a special unit of the Department of Technical Co-operation in 1961. As such, its terms of reference now include the promotion of international technical co-operation in the field of locust research and control, and the provision of facilities for visiting scientists and students for research and training. Thus in addition to special rooms for visitors, there is a conference room with sound cinematograph projection room attached, which is used for seminars and training courses.

Current research at the Centre covers three main fields—biology, biogeography and control. Biological

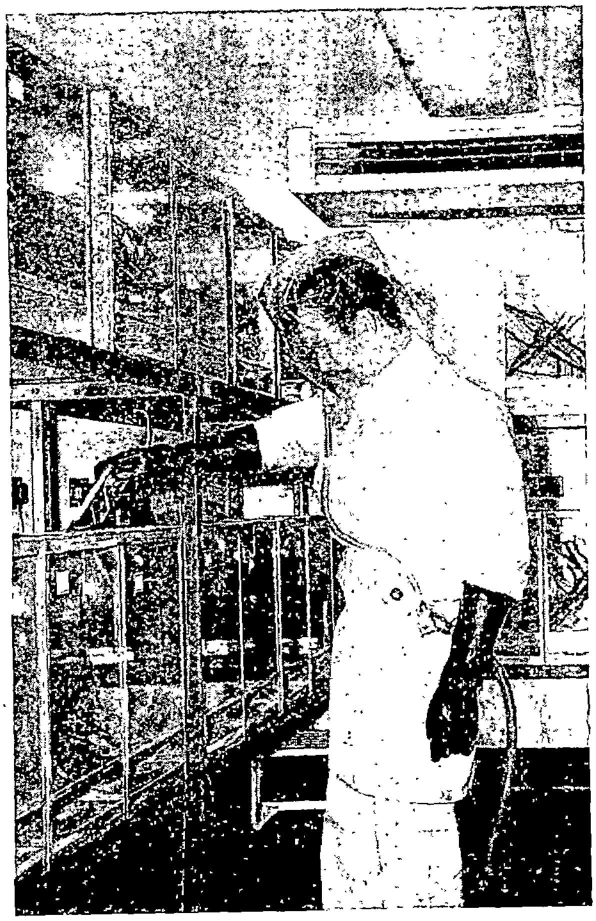

Fig. 1. A corner of one of the constant-temperature breeding rooms, showing a member of the staff wearing special clothing as a protection against locust allergens

research includes the taxonomy and identification of locusts and grasshoppers sent in by sources throughout the world; Dr. V. M. Dirsh is in charge of this work and, as already remarked, his section remains at the Entomological Department of the British Museum (Natural History), together with the Centre's extensive collection of specimens. The breeding facilities, in charge of Mr. Hunter-Jones, allow the rearing of a million or so locusts a year, and make it possible to investigate the life-histories of economically important locusts and grasshoppers. The experimental rooms enable the effects of environmental changes on the development, maturation and reproduction of locusts to be studied. A major effort is being directed to those aspects of locust behaviour and physiology which might ultimately lead to the development of new methods of control, such as the study of attractants and the hormone systems involved in locomotor and reproductive activity. This work is being conducted by Dr. P. T. Haskell, Dr. D. B. Carlisle and Dr. P. E. Ellis.

The examination of the biogeography of locusts has always been considered by the Centre as an essential basis for the strategy of their control. The Biogeographical Section, led by Miss Z. Waloff, is at present concerned with the analysis of historical data on the plagues and recessions of the desert locust, the initiation, development and decline of the last major plagues of the red and the African migratory locusts and the seasonal distribution and breeding of tree locusts in relation to rainfall and vegetation. A further project concerns the assessment of the economic importance of locusts, and involves the assembly and analysis of agricultural statistics and locust damage records.

Another section engaged on biogeographical work the Desert Locust Information Service, in charge Dr. R. C. Rainey. This section, which is also sponsor by the Food and Agriculture Organization of the Unit Nations, maintains the record of desert locust activi which has been built up in the Centre over the pa thirty-five years. Locust situation reports, sent regula to the Centre by countries affected by the desert locu are correlated with daily weather data supplied with t co-operation of the U.K. Meteorological Office and t World Meteorological Organization and form the ba for a monthly summary of the current desert loc situation and a forecast of expected developments wh is sent to countries in and around the invasion ar The section also carries out research on the influence climatic and meteorological factors on the desert locust

Research on locust control includes work undertak by the Field Research and Insecticide Sections. T former section, led by Mr. C. Ashall, is staffed entir by scientists with very long practical experience locust research and control in the field and it carries c field investigations of locust and grasshopper cont in close co-operation with overseas anti-locust organ ations and plant protection departments. Thus, officer from the section is now based in the Trucial Sta to carry out surveys of desert locust populations in t area and in other parts of the Arabian Peninsula. A visory and training visits are carried out in response increasing requests from overseas Governments; example, recently a preliminary survey of the red loc situation in Mauritius was begun, and in the past year t training courses have been given in the Sudan and th in Saudi Arabia.

The Insecticide Section, led by Mr. R. D. MacCu is concerned with testing new insecticides and inves ating the factors affecting the toxicity of insectici and their formulations to locusts. Recent laborat work has shown that the volatility of spray solvents c greatly influence their toxicity, and further experime are being undertaken to estimate the importance of t in control operations. A standard insecticide test kit for locusts has been prepared so as to enable susceptibility of locusts of the same species in differ regions of the world to be determined.

The section carries out field work concerned with testing and calibration of spray gear, the assessment control methods and the development of techniq for testing spray pick-up and residues, all of which is d overseas in co-operation with international locust org izations or plant protection departments.

The 'servicing sections' of the Centre include Statistical and Photographic Section, which advises the design of experiments, sampling techniques related subjects; the Training and Liaison Section, wh deals with home training courses, publications and pu relations; and the Library. The latter contains m than 13,000 separate publications on locusts and gr hoppers in more than twenty-five languages, aut catalogued with subject and species indexes. It looks a the photographic collection and the unique collectio taxonomic works on locusts and grasshoppers and publishes abstracts of current literature on locusts grasshoppers.

The Centre plays a leading part in the furtheranc international co-operation in locust control and rese and it has achieved world recognition as the pre-emi establishment for anti-locust investigations. The facilities at College House are worthy of this role. interesting to reflect, particularly at the present time w much attention is being directed to the problems of ai developing countries, that the Centre, paid for by British taxpayer, has for the past eighteen years pione international technical assistance in locust research control and exists solely for the benefit of ove territories.

SOUTHAMPTON MEETING OF THE BRITISH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE

By R. N. M. ROBERTSON

Secretary and Registrar, University of Southampton

THE British Association first met in Southampton in 1846, sixteen years before the opening of the Hartley Institution, in which the University of Southampton originated. In 1882 when the Association next came to Southampton the programme included a *soirée* at the "Hartley Hall" and in 1925 at the following meeting various sectional meetings were reported as having been held at the Hartley University College. The Hartley Institution, later known as the Hartley College, was incorporated in 1902 as the Hartley University College by the Board of Education. The *Centenary History of the University*[1] refers to the support of the British Association for the establishment of full-time technical colleges in all major towns aided by government and local grants, and it seems likely that this strengthened the Institution's case for help for this aspect of its work. New buildings in Highfield for the University College were opened by Lord Haldane in June 1914, but the establishment of a military hospital soon afterwards prevented a move from the old buildings in the High Street until 1919.

The fourth visit of the Association to Southampton, to be held this year during August 26–September 2, comes twelve years after the dissolution of the Hartley University College on the constitution of the University of Southampton by Royal Charter in 1952. *The Centenary History* is largely devoted to financial difficulties, as a result of which the buildings available to the College, when the British Association meetings were held in 1882 and 1925, were ill-equipped and to some extent unsuited to their purpose. This year's activities will mainly centre on new buildings erected in a period of unprecedented growth in student numbers, which justifies all the struggles of the past. In the session 1963–64 the student population has been 2,100, and, according to the plan approved by the University Grants Committee to meet the needs outlined in the Robbins Report, the numbers will increase to 4,000 by session 1967–68. No decisions have been reached about later expansion, but the confident hope is that Southampton will take its place as one of the multi-faculty universities of 8,000–10,000 students envisaged by the Robbins Committee. By 1967–68 sixty per cent of the students will be in the Faculties of Science and Engineering and further evidence of the swing in this direction is perhaps to be seen in the appointment of Prof. Kenneth Mather, of the University of Birmingham, to succeed the present vice-chancellor, Dr. D. G. James, at the end of session 1964–65 (*Nature*, 203, 24; 1964).

Southampton, Britain's principal ocean passenger port, and a major cargo centre, occupies a central position on the south coast of England within eighty miles of London. A borough for almost eight centuries, its history stretches back through settlements established by the West Saxons and Danes to the Roman port of Clausentum on the River Itchen. Canute was chosen as King by the Saxon Council at a meeting in the town in 1017, and the story of his attempt to turn the tide is reputed to be connected with one of his subsequent visits. In medieval times the prosperity of the port, with its interesting double tides, was founded on the wine and wool trades, but a period of decline followed until the town was transformed into a fashionable spa in the eighteenth century. The coming of the railway led to the rise of the transatlantic passenger trade, culminating in the completion of the New Docks in 1934. More recently Southampton has become a centre of the chemical industry, largely as the result of the siting of the Esso refinery at Fawley on the south side of Southampton Water. The refinery, the largest in Great Britain, produces 11,000,000 tons of petroleum products per annum and supplies nearly a quarter of the country's requirements. With the introduction of economic methods of converting waste material from the refinery into useful chemicals the growth of Fawley has led to the erection in adjacent sites of large chemical plants by such firms as Monsanto,

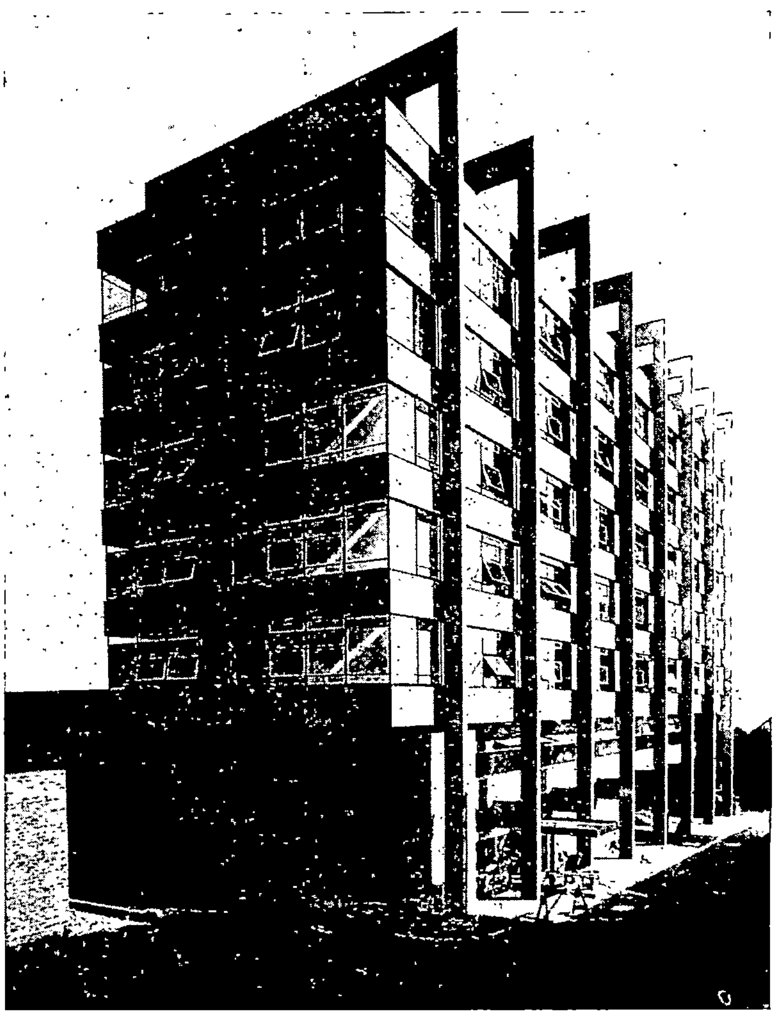

Fig. 1. New Chemistry Building, University of Southampton

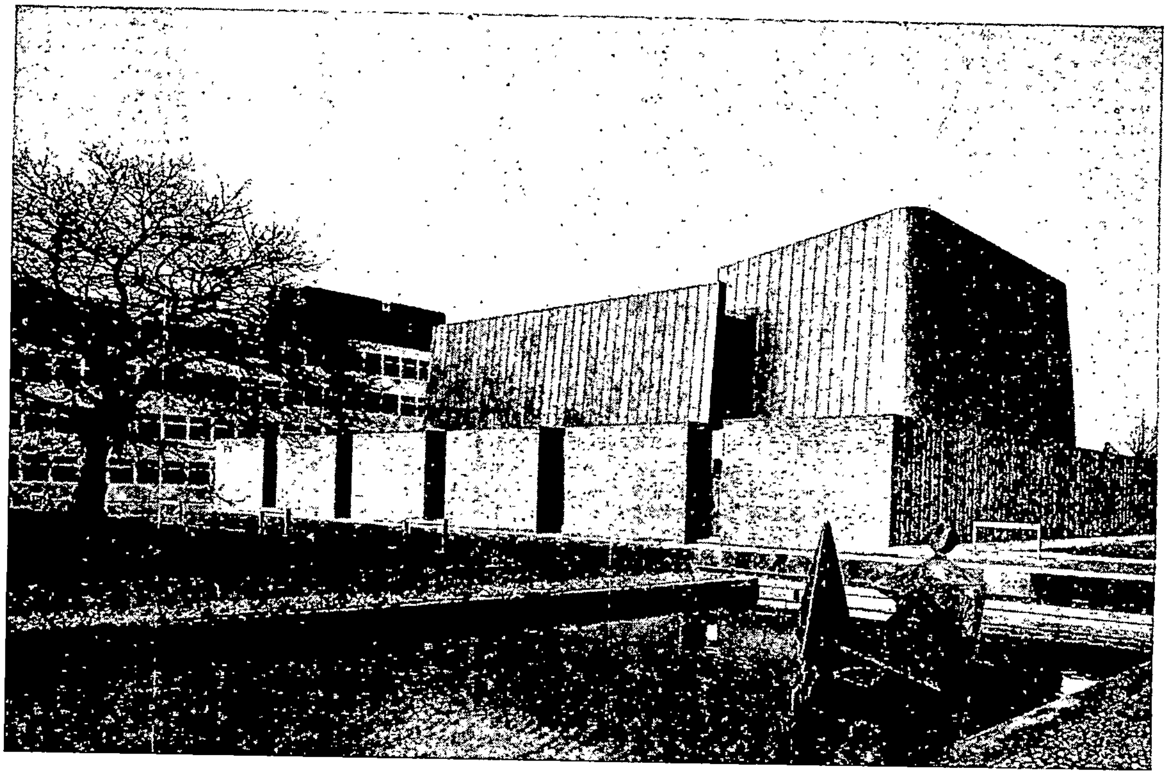

Fig. 2. Nuffield Theatre with Arts Building in the background

International Synthetic Rubber and Union Carbide. Local industry is not restricted to these activities and other firms with extensive plants in Southampton include AC-Delco, Standard Telephones and Cables, Mullards, Pirelli-General, British American Tobacco, Ford, Vickers-Armstrong, Hawker Siddeley and Thornycroft. In 1846, on the occasion of the first meeting, Southampton was described as "this beautiful and flourishing sea port" with considerable value to the naturalist and geologist. Although the description is still to some extent true, it must be emphasized that the area is now also one of great industrial significance.

These local interests of the city are well supplemented by the regional characteristics of Wessex, with its cathedral cities, country towns, forests, heaths and downs, the whole presenting a fitting setting for the 1964 meeting. The programme of excursions, general and sectional, is widely varied. There will be many opportunities to visit factories, industrial plants and other establishments not only in the city but also farther afield at the Royal Aircraft Establishment at Farnborough, the Road Research Laboratory at Crowthorne, Berks, the Atomic Energy Establishment at Winfrith and the National Institute of Research in Dairying at Reading. In addition to visits to Southampton Docks, including conducted tours of the R.M.S. *Queen Elizabeth*, there will be a specially organized day cruise of Southampton Water and the Solent. Historic buildings in Southampton feature in the programme as well as visits to the great cathedrals of Winchester, Salisbury and Chichester and to such notable country houses as Wilton, Longleat, Beaulieu, Breamore and Stratfield Saye. The Ordnance Survey office in Southampton will also be open to members. Natural and prehistoric features include the New Forest, Old Winchester Hill, Maiden Castle, the Furzebrook Nature Conservancy Reserves, the Isle of Wight and the Dorset Coast.

One of the first steps taken in planning the meeting was the appointment of Prof. F. J. Monkhouse, professor of geography in the University, as editor of *The Southampton Survey*, which has been compiled and published for the meeting. The first part of the Survey deals with the wider region of which the City of Southampton forms part, the whole of Hampshire, the Isle of Wight and the adjoining parts of Wiltshire, Dorset and West Sussex; the second part is concerned with the historical background both of the wider region and of the city; the third looks to present-day Southampton from economic, social and administrative points of view. A copy of the survey, which has been printed locally by the Camelot Press, will be presented to each member of the Association attending the meeting. This year copies may, if desired, be obtained by members in advance, and after the meeting they may be purchased on application to the University (35*s*. or 5 dollars, including postage).

The previous presidents at Southampton were Sir Roderick Murchison (1846), Dr. C. William Siemens (1882), and Prof. Horace Lamb (1925). The president of the 1964 meeting is Lord Brain (*Nature*, 199, 891; 1963), the distinguished neurologist and former president of the Royal College of Physicians, who will deliver an address on "Science and Behaviour". Before the address, the Chancellor of the University, Sir Keith Murray, former chairman of the University Grants Committee, will confer the honorary degree of doctor of science on Lord Brain and also on Sir Eric Ashby and Sir Cyril Hinshelwood.

The two evening discourses will be by Prof. W. J. G. Benyon on "The International Years of the Quiet Sun" and by Prof. A. S. Parkes on "Biological Aspects of the Population Explosion". There will also be a public lecture by Dr. A. T. J. Dollar on August 30, entitled "Island Volcano", which will cover the recent new volcanic island off the coast of Iceland. The presidential addresses in the sections will present the usual wide range of topics, many of particular interest to non-scientific members; but a new note will be sounded on August 31 with "Science in Science Fiction" by Prof. W. T. Williams of the University Department of Botany and some of his colleagues. This year, for the first time, the Council of the Association has made arrangements for live television transmissions of the morning sessions of a number of the sections.

By special arrangements with Southern Television, which covers an area from Bridport to Dover with an extensive hinterland, there will be about fifteen hours in all of transmissions from the University's Nuffield Theatre (Fig. 2). This new Theatre, which was built largely with the aid of a grant of £130,000 from the Nuffield Foundation, has a seating capacity of 500 and was opened earlier this year by Dame Sybil Thorndike. In addition to television presentations, scientific film shows and an Open Forum for young people will also be given there.

The exhibitions at this year's meeting include one staged by the Ordnance Survey in the entrance hall of the University Main Building, which will contain a comprehensive display of their work. Members of the staff of the Survey will be in attendance to give practical demonstrations of some of the techniques used in field surveying and cartography. The National Book League will stage an exhibition "Science for All" together with a supplementary exhibition on the Social Sciences. There will also be special demonstrations set up by the Departments of Zoology and Botany and by the Institute of Science Technology in the Department of Chemistry (Fig. 1), and the University Library will feature exhibitions of books on Botanical Illustrations and the local history of Southampton. The hydraulic model of Southampton Water, which is housed in a special building, will be demonstrated daily by the Civil Engineering Department, and in the Electronics Department a number of commercial and government organizations will sponsor an exhibition of some recent developments in the fields of microminiature circuits, electrical generation and communications equipment.

The young people's Science Fair will be held in the new Southampton College of Technology, where more than 130 projects from 61 secondary schools and three training colleges will occupy laboratories and demonstration rooms on six floors. There will also be illustrated lectures for young people in the Guildhall on four days of the meeting by Prof. R. V. Jones, Dr. N. Tinburger, Dr. H. A. Thomas and Dr. E. J. Ambrose. Prof. L. Dudley Stamp will be chairman of the Open Forum in the Nuffield Theatre and the panel will consist of Dr. J. D. Cartney, Dr. V. Milledge, Mr. D. E. Broadbent and Prof. W. T. Williams. The social activities of the week will include two evening receptions given by the City Council in the Guildhall. The University will give a Garden Party to all members in the gardens of South Stoneham House, an early eighteenth-century mansion now used as a University Hall of Residence, and a number of other functions will be offered by private organizations, including a particularly appropriate gesture of hospitality, lunch on board R.M.S. *Capetown Castle*.

The local organizers in Southampton feel that they are well prepared for the meeting and they anticipate that it will not only be the best of the Southampton meetings but also one of the outstanding meetings in the history of the Association.

---

NEWS and VIEWS

The Royal Society: Research Appointments

The Royal Society recently agreed to co-operate with Wadham College, Oxford, in setting up a Royal Society research fellowship in the biological sciences at Wadham College. The establishment of this post marks the three hundred and fiftieth anniversary of the foundation of Wadham College and also the Royal Society's past historical associations with the College. The Research Fellow will be a full official Fellow of Wadham College and the appointment has been made for a period of five years from October 1. It has now been announced that Dr. D. C. Smith, university demonstrator in the Department of Agriculture at the University of Oxford, has been appointed to this post. Dr. Smith will carry out research in the physiology of lichens.

The Royal Society has also announced that the Foulerton Gift research fellowship, for two years in the first instance from October 1, has been awarded to Dr. J. J. B. Jack, at present house surgeon at the Radcliffe Infirmary, Oxford, to enable him to work on excitation and inhibition in the spinal cord at the University Laboratory of Physiology, Oxford.

Galileo Celebration

On the evening of July 9 the Royal Society celebrated the quater-centenary of the birth of Galileo Galilei (*Nature*, 201, 563; 1964) with a special Conversazione held in the Society's apartments at Burlington House. Among the guests were representatives of the Accademia Nazionale dei Lincei, of which Galileo was a member, the British–Italian Society, the British Society for the History of Science and the British National Committee for the History of Science. Among the exhibits was a rare collection, arranged by Prof. E. N. da C. Andrade, of books by and about Galileo, including a number of early English books in which mention of Galileo is made, including *Paradise Lost* and *Areopagitica* by John Milton. A few of the experiments which Galileo himself carried out relating to fundamental laws of mechanics were repeated by the staff of the Royal Institution. Other exhibits compared what Galileo saw through his telescope with modern achievements on the same subject. For example, his description of sunspots is contrasted with contemporary photographs obtained by the Royal Greenwich Observatory, and the Department of Astronomy, University of Manchester, likewise compared up-to-date knowledge of lunar topography with that observed by Galileo. The Nuffield Radio Astronomy Laboratories, Jodrell Bank, University of Manchester, described some recent radio astronomical work relating to Venus and to radio sources in the Milky Way, both Venus and the Milky Way being subjects of observation by Galileo. The National Physical Laboratory demonstrated a reversible pendulum for the absolute determination of gravity, and Mr. D. G. King-Hele, of the Space Department of the Royal Aircraft Establishment, in a display showed what could be learned about the upper atmosphere and its dependence on solar activity as determined from the orbits of artificial Earth satellites.

Research on Metal Extraction and Mineral Processing

In a written answer in the House of Commons on June 25, the Secretary of State for Education and Science, Mr. Q. Hogg, stated that the decision to transfer forty staff of all grades employed on work on the extraction of metals from the National Chemical Laboratory to the Warren Spring Laboratory followed the Government's acceptance of a recommendation of the Brundrett Report on Technical Assistance for Overseas Geology and Mining. Of these forty, three junior members resigned before the decision was announced and one more senior had resigned since; eight had asked for transfer elsewhere. The Director of the National Chemical Laboratory gave the Department no reason for his resignation, but it is understood that he disagreed with the decision to implement this recommendation of the Brundrett Committee. While Mr. Hogg greatly regretted Dr. Mitchell's decision, he was satisfied that the national interest would best be served by arranging, as the Brundrett Committee recommended, for the work on extraction of metals and that on mineral processing to be integrated under the same research direction.

The Council for National Academic Awards

In a written reply on July 2 to a question by Mr. Julian Critchley, Mr. Hogg announced the membership of the new Council for National Academic Awards under the chairmanship of Sir Harold Roxbee Cox (*Nature*, 201, 975; 1964): The Viscount Caldecote (deputy chairman, English Electric); Mr. W. F. Cartwright (managing director, Steel Co. of Wales); Mr. Michael Clapham (director of Imperial Chemical Industries); Sir James Cook (vice-chancellor, University of Exeter); Mr. B. Downs (head of Department of Mechanical Engineering, Loughborough College of Advanced Technology); Miss Helen L. Gardner (reader in English literature, University of Oxford); Dr. D. E. R. Godfrey (head of Mathematics Department, Woolwich Polytechnic); Mr. H. N. Henry (principal, Paisley College of Technology); Prof. J. Lamb (professor of electrical engineering, University of Glasgow); Mr. J. Russell Lang (chairman, G. and J. Weir, Ltd., Glasgow); Dr. Kathleen Ollerenshaw (Manchester City Councillor and member of Manchester Education Committee); Dr. O. G. Pickard (principal, Ealing Technical College); Sir Arnold Plant (professor of commerce, University of London); Mr. R. H. J. Rhodes (vice-principal, Leeds College of Commerce); Prof. G. D. Rochester (professor of physics, University of Durham); Sir Lionel Russell (chief education officer, Birmingham); Dr. J. Topping (principal, Brunel College of Advanced Technology); Mr. D. Vitkovitch (head of Electrical Engineering Department, Nottingham and District Technical College); Dr. G. E. Watts (principal, Brighton College of Technology); Mr. R. E. Wood (principal, Leicester College of Technology and Commerce); Dr. E. G. Woodroofe (joint vice-chairman, Unilever). The new Council will take over the responsibilities of the National Council for Technological Awards as soon as it is in a position to do so, but the latter will continue to administer the Diploma in Technology in the meantime.

The Commonwealth Development Corporation

The annual report of the Commonwealth Development Corporation for the year ended December 31, 1963, welcomes the Commonwealth Development Act, 1963, which became law in July 1963 (Pp. vi + 102. London: H.M.S.O., 1964. 6*s*. 6*d*. net). The Act restored the Corporation's full powers of operation in all those countries within the Commonwealth which had achieved independence since the Corporation was established in 1948. The Corporation's area of activity had been contracting year by year and, now that the area of investment has been restored to that of 1948, it should again be possible to expand the volume of investment. The useful future of increasing activity now foreseen should be beneficial in sustaining the essential morale of the staff, which in some territories overseas had faced a year of danger with a steadiness to which the report pays tribute. Ten new projects involving a total commitment of £6,585,000 were approved during the year; three large projects involving £3,400,000 are in independent Commonwealth countries. Plans for further investment in existing projects have been approved for a total of £3,860,000; however, these figures do not give full weight to new projects approved by local development companies in which the Corporation has an interest. The falling away of new project approvals in 1962 was reflected in a further contraction of new investment from £9·5 million in 1962 to £6·8 million in 1963, but the whole of this new investment was financed from sources other than additional drawings from the Treasury, to which there was a net repayment of £100,000, in addition to the £629,000 formula payment in reduction of frozen balances. The operating surplus of £4,751,622 was £391,000 greater than in 1962, but the present arrangements do not give sufficient margin against the commercial and other risks that the Corporation is bound to run; the operating margin continues to narrow. Besides loans for public utility (infra-structure) purposes and investments in large-scale agricultural, industrial and estate projects, the Corporation's investment is increasingly directed to projects involving association with and support of the peoples of the countries in which it operates. Recently, a particular aim has been to make available to small farmers some of the benefits of present-day scientific advances in growing, handling and processing tropical crops.

Qualifications in Biology

The Institute of Biology has agreed to join with the professional institutes for other sciences and the Ministry of Education in a scheme for an Ordinary National Certificate in the Sciences. This will replace the Ordinary Endorsed Certificate in Biology and Ordinary National Certificate in Chemistry and Physics. Those intending to proceed to a Higher National Certificate in Applied Biology will study biology to a higher level than mathematics, physics and chemistry. It is likely that, of the time available for scientific subjects, one-half will be available for biology, one-quarter for chemistry and one-quarter for mathematics and physics. The Institute is represented on the Joint Committee for the Ordinary National Certificate in the Sciences by Prof. C. G. C. Chesters and Dr. R. J. Terry. The Committee will later issue rules and notes for guidance with the view of courses commencing in September 1965. The Institute has also been considering means of admitting persons to membership of the Institute as a result of an examination set by the Institute. It is envisaged that the examination will be taken after three years part-time study by persons who enter the course with a Higher National Certificate in Applied Biology. There would be a Part 1 examination at the end of the first year, at which candidates would take papers in the principles of biology and in a special subject. The Part 2 examination would be on the special subject alone. The subjects at present being considered are biochemistry, entomology, microbiology, pharmacology and plant pathology. For these subjects, panels are preparing syllabuses. A meeting was recently held with representatives of technical colleges and of the major employers of biologists at which comments were received on the scheme. A preliminary enquiry shows that some twenty colleges hope to be able to offer courses with a total intake of some 150 students. Courses leading to the examination for membership of the Institute of Biology will commence in September 1965.

The Macaulay Institute for Soil Research

The thirty-third annual report of the Macaulay Institute for Soil Research for 1962–63 summarizes the work in progress and includes a list of seventy papers, published or submitted for publication (Pp. 56. Craigiebuckler, Aberdeen: The Macaulay Institute for Soil Research, 1964). The primary aim of the research continues to be the addition to fundamental knowledge of soils and soil : plant relationships supported by investigations directed towards the maintenance or improvement of soil fertility. Of the wide range of investigations described, only a short selection is needed to indicate the nature of the activities in the various departments. Electron microscopy and diffraction have been added to the methods for soil mineralogy investigation; pollen analyses of peat deposits are intended to supplement scanty records of vegetational history, and the physical properties of peat to help in investigations of tree growth. The soil survey has completed a further 580 square miles on the 2·5-in. scale, and another memoir (*Country Round Aberdeen, Inverurie and Fraserburgh*) has been published. Emphasis is laid on the need for more information on the trace element contents of different species at different stages of growth and on the possible dangers of lead toxicity. The interactions between major and trace elements on ion transport and exchange in plant tissues continue to receive attention and a start has been made on the role of vacuolar osmotic potential in nutrient uptake. Selected soil groups are being used for evaluating the properties that govern soil productivity, and investigations of responses to fertilizers have included methods and times of application.

The Furniture Industry Research Association

The third annual report of the Furniture Industry Research Association shows that, during 1963, a significant increase in membership occurred, and that total membership now amounts to 712 (Pp. 16. Stevenage: The Furniture Industry Research Association, 1964). This includes 538 firms registered with the Furniture Development Council, which cover about 80 per cent by value of the turnover of the industry. Considerable progress is reported on all present research projects covering such topics as the determination of the loads in chair frames, causes of show-through in veneered chip-board, the checking of veneers, and the investigation of the properties of flexible polyether foams. Work has been completed on polyvinyl acetate adhesives and on the development of a glossing-up test for matt lacquers. The optimum conditions for spray-gun operation have been determined by relating the quality of the finish to the waste of lacquer through fog and bounce. About 20 per cent of the research staff investigators have been concerned with the investigation of *ad hoc* enquiries, such as the performance testing of prototype furniture, causes of warping of panels, comparative testing of various finishes, the critical examination of chairs from the point of view of comfort, the suitability of different timbers, the noisiness of table tops and various fault investigations. The Technical Information Service has been called on to meet an increasing demand. A total of 2,200 enquiries submitted by 542 organizations has been dealt with. A new publication series, known as *FIRA Notes*, has been introduced with the view of giving in easily digestible form concise and up-to-date information drawn from the Association's own sources and elsewhere.

Rugby School Natural History Society

The ninety-seventh issue of the report of the Rugby School Natural History Society contains details of the archæological excavations carried out at Caves Inn, near Shawell, in 1963 by the Rugby Archæological Society and members of Rugby School (Pp. 22+2 plates. Rugby: Rugby School Natural History Society, 1964). The hill by Caves Inn Farm is referred to as Tripontium and is mentioned in the sixth itinerary of Antonius. Historians, through the ages, have used this itinerary in conjunction with the name of the hill to try to locate it. While there is no firm evidence of its identification, its situation in Roman miles fits the information in the itinerary. The evidence found so far suggests that the site consisted of a 'Mansio', surrounded by a settlement. Another article in the report includes some observations of solar activity made at the Temple Observatory during the summer term, 1963, as well as an account of the work of the Conservation Corps at Scolt Head by I. R. Whitehead.

The Cole Library: University of Reading

The books on zoology and early medicine, collected by the late Prof. F. J. Cole, have now been moved from his home at Kingwood, Oxfordshire, to the new Library Building of the University of Reading at Whiteknights Park, where they occupy an air-conditioned room in the special collections section on the fifth floor (see also *Nature*, 188, 1148; 1960). The Cole Library comprises eight thousand volumes dating from 1472 to the present day, and it contains many rare items. Author, title and subject catalogues were prepared by Prof. Cole, and are a valuable aid to the reader. A chronological catalogue down to the end of the eighteenth century is now being made by Dr. N. B. Eales, and this will include biographies and translations.

Scottish Journal of Geology

The first part of a new geological journal, the *Scottish Journal of Geology*, is due to appear in the autumn of this year. The new journal is the result of an amalgamation of the *Transactions of the Geological Society of Edinburgh* and the *Transactions of the Geological Society of Glasgow*. The Councils of both Societies consider that the new journal will provide a better forum for the presentation of the scientific work of the two Societies and of other work on Scottish geology. They also intend to continue their policy of encouraging the publication of geological papers of general or specialist interest. The journal will be published three times a year. Subscription rates will be £4 per annum for institutional subscribers and 30*s*. per annum for Fellows of either Society. Enquiries about subscriptions or editorial matters should be addressed to the Editors, *Scottish Journal of Geology*, Tweeddale Court, 14 High Street, Edinburgh.

The Longest Road

The Trans-Canada Highway, the longest paved road in the world, which stretches for 5,000 miles (with two short ferry-breaks) from St. John's, Newfoundland, to Victoria, Vancouver Island, was originally opened in 1962, and has already transformed the conception of east-west direct communication by road in the Dominion. It is now practicable for Canadians to motor across this vast territory without leaving their own country. The first car-ferry is across the Gulf of St. Lawrence to Cape Breton Island. This is now artificially joined to Nova Scotia by a causeway constructed by literally filling in the one mile wide and 200-ft. deep Canso Strait between Cape Breton Island and the mainland with some 5 million cubic yards of rock, an engineering feat of no mean order, considering that bridging this gap, often subject to fierce spring tides and ice jams, was abandoned as being an impracticable task. From Nova Scotia the highway passes through New Brunswick to Quebec, thence via Montreal, across Ontario by Ottawa north of the Great Lakes by Sault Sainte Marie and Wawa to Fort William. In this stretch another great engineering triumph is recorded. Between Sault Sainte Marie and Fort William, a distance of some 400 miles, there occurs a wilderness area called by the Canadians 'The Gap'. Before the advent of this great highway, this feature had constituted a barrier which had virtually split the Dominion in two; its avoidance was only possible by following northerly loop-roads adding hundreds of miles to the distance to be traversed. In a vividly written and illustrated article in *The Lamp* (quarterly magazine of the Standard Oil Company of New Jersey, 46, No. 1; 1964), the hazards of this wilderness are well summed up: "The Gap itself was just 164 miles across, but it was split up by more than a hundred rivers, thousands of lakes, deep ravines, granite ledges—and muskeg. Muskeg is a Canadian highway engineer's peculiar nightmare. It is seemingly bottomless mud and silt, sometimes a mile deep, which freezes solid in winter but in summer becomes quicksand. Muskeg can swallow men and machinery—even roads. One section of the Trans-Canada, representing an entire day's work, disappeared without a trace before the next sun came up." From Fort William, the highway traverses Manitoba by Winnipeg, Saskatchewan via Regina, thence to Calgary, Alberta, into British Columbia, here through the most difficult section, Rogers Pass, 4,335 ft. O.D. with Rocky Mountain peaks rising 10,000 ft. on either side. At Vancouver a short sea ferry completes the journey along this amazing road to Victoria, Vancouver Island.

Clare Hall: a New Development of Clare College, Cambridge

CLARE COLLEGE has decided to promote within the College a new development to be known as Clare Hall. The intention is that Clare Hall shall make a contribution towards meeting present-day Cambridge needs by providing a new graduate society for resident and visiting scholars. Its fellowship is designed to bring together four categories: (1) scholars holding appointments in the University or in research institutions in Cambridge, whose subjects may not be in great demand for undergraduate teaching; (2) post-doctoral and other senior research workers; (3) visiting scholars in Cambridge on study-leave; (4) Research Fellows, elected from among more senior research students. When the new society has been established, a body of research students who are not Fellows will be added. The University has a petition before the Queen-in-Council, asking for a repeal of the University Statute which excludes women from membership of men's Colleges. Subject to approval being given to this petition, fellowships in Clare Hall will be open to men and women on equal terms. Clare Hall will be legally part of Clare College, governed by statutes of the College. The Society will consist of about forty Fellows of Clare Hall, who will also be bye-Fellows of Clare College. It will be governed by a Council composed of five Fellows of the Hall, five Fellows of the College, the Warden of the Hall, and the Master of the College as chairman. It is proposed that the buildings for Clare Hall, which will include flats, studios, a seminar room, and dining rooms, will be on a site within five minutes' walk of Clare College, where the Hall will be able to develop an identity of its own and to maintain, socially and intellectually, a close relationship with the College.

The Governing Body has recorded its intention to elect into fellowships of Clare Hall and bye-fellowships of Clare College the following: Dr. T. E. Armstrong, Mr. R. W. David, Mr. E. P. M. Dronke, Miss M. B. Hesse, and Dr. W. H. Taylor.

Clare College has received from the Old Dominion Foundation of New York an endowment of 200,000 dollars. The income from the endowment will be used to subsidize research fellowships and visiting fellowships at Clare Hall.

The Night Sky in August

NEW moon occurs on Aug. 7d 19h 17m U.T. and full moon on Aug. 23d 05h 26m. The following conjunctions with the Moon occur: Aug. 2d 03h, Jupiter 2° N.; Aug. 4d 16h, Venus 5° S.; Aug. 4d 23h, Mars 0·2° N.; Aug. 23d 07h, Saturn 3° N.; Aug. 29d 13h, Jupiter 2° N. Venus is in conjunction with Mars on Aug. 28d 11h, Venus being 4° S. Mercury is too close to the Sun for observation. Venus is a morning star, rising at 1h 25m, 1h 5m and 1h 10m on August 1, 15 and 31, respectively. Its stellar magnitude is $-4·1$; its distance from the Earth increases during the month from 46 to 67 million miles and the visible portion of the apparent disk from 0·320 to 0·516. Mars rises at 1h 05m, 0h 50m and 0h 35m at the beginning, middle and end of the month, respectively. Its stellar magnitude is $+1·7$; conditions for observation are not yet favourable. Jupiter rises at 23h 05m, 22h 15m and 21h 15m on August 1, 15 and 31, respectively. It is near the boundary of Aries and Taurus, its stellar magnitude is $-2·0$ and its distance from the Earth on August 15 is 456 million miles. Saturn is above the horizon most of the night. It is in Aquarius and in opposition on August 24. Its stellar magnitude is $+0·6$ and its distance from the Earth on August 15 is 816 million miles. Occultations of stars brighter than magnitude 6 are as follows, observations being made at Greenwich: Aug. 22d 00h 24·2m, φ Cap. (disappearance); Aug. 28d 23h 18·2m, 147 B. Ari. (reappearance). The Perseid meteors are active during July 27–August 17, with maximum on August 12. The radiant is near R.A. 3h 04m, Dec. $+58°$; conditions for observation are very favourable.

Announcements

PROF. PAUL PHILLIPS, of the University of Wisconsin, Madison, Wis., has been awarded a "medal of merit" by the Istituto Sperimentale "L. Spallanzani", Milan, in recognition of his contributions to the development of a practical method for artificially inseminating cows and for research on mineral elements in nutrition.

THE New Zealand Department of Scientific and Industrial Research has issued a list of printed publications, indicating those out of print and where those still in print can be obtained; more than 70 are publications of the Geological Survey and more than 150 Research Bulletins of the Department (*List of Publications*. Pp. 35. Wellington: Government Printer, 1964).

A CONFERENCE on "The Use of Film in Higher Education and Research" will be held at the College of Advanced Technology, Birmingham, during September 9–11. Further information can be obtained from P. D. Groves, Department of Chemistry, College of Advanced Technology, Gosta Green, Birmingham 4.

A SERIES of lectures on "Plasma Physics and its Applications in the Field of Thermo-nuclear Reactions and Electrical Power Generation" will be held at Sunderland Technical College during September 8–11. Further information can be obtained from the Physics Department, Sunderland Technical College, Sunderland.

A COURSE on "The Genetics and Physiology of Bacterial Viruses" will be held under the auspices of Unesco and the International Cell Research Organization, at the International Laboratory of Genetics and Biophysics, Naples, during September 11–October 9. Further information can be obtained from the International Laboratory of Genetics and Biophysics, Casella Postale 104, Naples.

THE fifth international symposium on "Gas Chromatography", organized by the Gas Chromatography Discussion Group of the Institute of Petroleum, will be held in Brighton during September 8–10. The programme will include sessions on: techniques of separation and identification; column design; exploitation of molecular interactions. Further information can be obtained from the Organizing Office, Fifth International Symposium on Gas Chromatography, 61 New Cavendish Street, London, W.1.

A SECTIONAL meeting of the World Power Conference on "The Struggle against Losses in the Field of Energy Economics" will be held in Lausanne during September 13–17. The general theme of the meeting will be divided into the following sections: general aspects; avoidance of losses in conversion; avoidance of losses in fuel transport and power transmission; avoidance of losses in utilization of energy. Further information can be obtained from the Swiss National Committee, World Power Conference, Plaza B, Petit Chêne 38, Lausanne.

THE fifteenth international Astronautical Congress will be held in Warsaw during September 7–12. The programme will include sessions on: flight programmes; propulsion techniques; navigation; lunar international laboratory; bioastronautics; power systems for space vehicles; celestial mechanics and astrodynamics; physical problems of re-entry into planetary atmosphere; meteorological satellite systems; communication satellite systems; geodetic satellite systems; ground installations; education in astronautics; space vehicles in an ionized medium. Further information can be obtained from the International Astronautical Federation, 250 rue Saint-Jacques, Paris 5.

WELLCOME HISTORICAL MUSEUM AND LIBRARY

DR. F. N. L. POYNTER, formerly chief librarian of the Wellcome Historical Medical Library has been appointed a director to take charge of both the Wellcome Historical Medical Museum and the Historical Medical Library. His appointment is part of a general reorganization following the retirement of Dr. E. Ashworth Underwood as director of the Wellcome Historical Medical Museum.

Dr. F. N. L. Poynter joined the staff of the library as assistant librarian in 1930 when Sir Henry Wellcome was himself director of the Museum and Library. He became sub-librarian in 1938, deputy librarian in 1946 and chief librarian in 1954. He received his training as a medical historian from the late Prof. Max Neuburger. In addition to his other duties he is secretary-general of the International Academy of the History of Medicine and honorary secretary of the Faculty of the History of Medicine of the Society of Apothecaries. He is the author of a number of books and more than a hundred papers on the history of medicine.

The Wellcome Historical Medical Museum and the Historical Medical Library are housed in the Wellcome Building in Euston Road, London. Both are based on collections initiated by the late Sir Henry Wellcome, who died in 1936. The Library contains approximately 250,000 printed books, pamphlets and journals, 10,000 manuscripts (of which half are in oriental languages) and 100,000 autograph letters of medical and scientific interest. The Museum contains what is probably the most comprehensive collection yet made of scientific instruments and antiquities of interest for the History of Medicine.

As part of the reorganization also, Dr. Edwin Clarke has been appointed medical historian to the Museum and Library and Mr. J. W. Barber-Lomax is to be administrative officer and veterinary historian. Dr. Clarke was formerly associate professor of the history of medicine in Yale University. Mr. Barber-Lomax, who is one of the leading veterinary historians in Great Britain, was formerly manager of the Professional Services Department, Veterinary Division of the Wellcome Foundation, Ltd.

Mr. E. Gaskell, formerly sub-librarian, has been elected librarian of the Historical Medical Library and Mr. E. Freeman sub-librarian.

Dr. Ashworth Underwood retired from the Wellcome Historical Medical Museum this year after nearly eighteen years as its director. Despite the frustrations of space restriction, resulting primarily from the War, Dr. Ashworth Underwood was able to keep a representative exhibition open for the public and was always striving for the proper deployment of the collection so that full use could be made of it. Important exhibitions of topical subjects were regularly arranged by him during his term of office and his great knowledge of the subject enabled him to give much help to many students of the history of medicine.

Before his appointment as director of the Historical Medical Museum Dr. Ashworth Underwood had been medical officer of health for West Ham and an honorary lecturer in the Department of the History of Science and Philosophy in University College, London. He has published many papers and books, among them the second edition of Singer's *Short History of Medicine*.

BALTHAZAR VAN DER POL GOLD MEDAL FOR SCIENTIFIC RADIO

DURING the general assembly of the International Scientific Radio Union (URSI) in Tokyo, September 1963, an evening was devoted to honouring the memory of the late Dr. Balth. van der Pol (1889–1959), who had devoted an important part of his numerous activities to the growth of URSI, in which he was so keenly interested. The occasion was the first presentation of the Gold Medal founded by the generosity of Mrs. van der Pol in memory of her late husband. In consultation with the Board of Officers of URSI, it was decided that the Medal was to be awarded to an outstanding radio scientist who, during the three-year period preceding the year of each general assembly, has made a valuable contribution in one of the fields of activity of the Union either by his research work, discoveries or achievements, or by any other activity.

In a volume recently published (June 1964) under the title *Van der Pol Memorial Lecture 1963*, by the Secretary-General of URSI (7 Place Emile Danco, Bruxelles, Belgium), the proceedings at this special meeting are recorded in full. After a short opening address by the president, Dr. R. L. Smith-Rose, a review of the life and scientific work of Balthazar van der Pol was given by Prof. Ch. Manneback, treasurer of URSI.

He recalled that, after graduating at the University of Utrecht in 1916, van der Pol went to England, where he worked with Prof. (Sir Ambrose) Fleming in the University of London, and with Prof. (Sir J. J.) Thomson in the Cavendish Laboratory, Cambridge. He returned to the Netherlands in 1919, and, after obtaining his doctor's degree at Utrecht, he joined the research laboratories of the Philips Company at Eindhoven in 1922. He remained there until 1949, when he was appointed the first director of the International Radio Consultative Committee (CCIR) in Geneva. After his retirement in 1956, he was visiting professor in the University of California, Berkeley, and, in 1958, in Cornell University, Ithaca.

Following this exposition at the ceremony in Tokyo, the first van der Pol Gold Medal was then presented to Prof. Martin Ryle by Mrs. van der Pol in recognition of his leadership of the radio astronomy group at the Mullard Observatory of the Cavendish Laboratory, Cambridge. Remarking on the appropriateness of the award, Mrs. van der Pol recalled the period in 1917 during which her late husband had worked at the Cavendish Laboratory, where he formed a life-long friendship with Dr. (Sir Edward) Appleton and other British scientists. The new group under Prof. Ryle has made outstanding contributions to astronomy, problems of cosmology, and to scientific radio. In particular, the Cambridge scientists have developed new aerial systems, especially suited to radio astronomical research. Following his acceptance of the Medal, Prof. Ryle gave a lecture on "Giant Radio Telescopes", which is reproduced with diagrams and photographs in the volume just published. In the course of his lecture, Prof. Ryle outlined the two main problems of radio astronomy: the limited resolving power obtainable compared with optical astronomy; and the extreme weakness of the signals to be received. A brief description was given of the design and performance of the three telescopes operating on the principle of 'aperture synthesis', which was developed at Cambridge. Some details were also given of a fourth and considerably more powerful instrument under construction.

After the president had thanked Prof. Ryle for his lecture, Mrs. van der Pol presented a second Gold Medal to Colonel Ernest Herbays, secretary-general of URSI, in recognition of his continuous and devoted service to the Union since 1928. In the volume now published recording these proceedings, Colonel Herbays very appropriately provided a concluding section outlining the history of the Union since the first meeting in 1912 of a few scientists interested in the investigation of the phenomena associated with 'electric waves'.

The production of this little volume is excellent in every way; and it forms a worthy memorial to the achievements of URSI and the part played in them by the late Dr. B. van der Pol. R. L. SMITH-ROSE

CANADIAN SOCIETY OF PLANT PHYSIOLOGISTS

THE 1964 annual meeting of the Canadian Society of Plant Physiologists—la Société Canadienne de Physiologie Végétale—was recently held in Kingston, Ontario. The host institute was Queen's University.

The proceedings opened, on June 4, with a symposium on respiration under the chairmanship of Prof. Dorothy F. Forward (University of Toronto). Dr. D. F. Parsons (Department of Medical Biophysics, University of Toronto) discussed his recent investigations of the structure and junction of mitochondrial membranes, using a negative staining technique for electron microscopy. Two types of projecting sub-units were found, one on the outer membrane, consisting of 60 Å hollow cylinders, and the other on the cristæ, consisting of 90 Å mushroom-shaped structures. The latter structures have been found in a wide variety of plant and animal tissues. These sub-units are protein, but do not contain cytochromes. There is evidence for the presence of a flavoprotein and an ATPase. The sub-units may be associated with oxidative phosphorylation.

Dr. W. D. Bonner, jun. (Johnson Research Foundation, University of Pennsylvania), presented a paper on electron transport in plant mitochondria. He discussed the large number of cytochromes which have been described, and the difficulties in their characterization. Two *c*-type, three *b*-type and three *a*-type cytochromes are present in the mitochondria of all plant species, regardless of the respiratory characteristics. At normal concentrations of oxygen, when ADP is limiting (state-4 conditions), oxidation by plant mitochondria is not inhibited by hydrocyanic acid (HCN) or carbon monoxide (CO). However, when ADP is in excess (state-3 conditions), HCN + CO reduces the rate to that of state-4. State-4 rate corresponds to the 'ground respiration' of plant physiological literature. This is completely inhibited at low concentrations of oxygen by HCN and CO; the same is true in mitochondria which show HCN and CO insensitive respiration (skunk cabbage). Kinetic analysis suggests that oxygen reacts with two separate oxidases. This is supported by optical demonstration of two CO (O_2) binding pigments. The presence of a second CO-binding pigment provides an explanation for both 'ground respiration' and 'cyanide insensitive respiration'.

The symposium was completed by a paper by Prof. G. Krotkov (Biology Department, Queen's University) on the effect of light on respiration, thus continuing the development of the symposium subject from the sub-cellular structural level to that of the physiology of the whole organism. The question of whether respiration is affected by light has in the past been answered by indirect means. The techniques used in Dr. Krotkov's laboratory made it possible to show that light and dark respiration are two different processes. 'Photorespiration', or evolution of carbon dioxide in light, involves different pathways of metabolism, perhaps utilizing glycollic acid metabolism. Corn, a plant of exceptionally high productive ability, has no photorespiration, and appears to lack co-factors for glycollic acid oxidation. Corn does not 'waste' products of photosynthesis in respiration while it is illuminated, and is thus more efficient than other plants.

Six half-day sessions (two sessions always running concurrently) were devoted to contributed papers. A closely knit group of papers on translocation originated from the laboratories of the Division of Biosciences, National Research Council, Ottawa, under the direction of Dr. P. R. Gorham and Dr. D. C. Mortimer, and from the laboratory of Dr. G. Krotkov and Dr. C. D. Nelson at Queen's University, the host institute. Dr. Mortimer's results showed that downward translocation of photosynthate occurred at greatly varying rates and intensities in different vascular bundles of a leaf, which thus had to be analysed separately. The Queen's University group showed that translocation of photosynthate is under hormonal control, and that there is selective and preferential translocation of certain sugars.

The session on nitrogen included two papers from the laboratory of Dr. W. G. Boll (McGill University, Montreal) on the ability of ethanolamine to replace vitamin B_6 in the nutrition of excised tomato roots, and on the biochemical mechanisms associated with this ability. An interesting paper from the laboratory of Dr. C. L. Mer (Imperial College of Science and Technology, London (now visiting at Harvard University)) provided a nutritive hypothesis for growth responses in oat seedlings which precludes the necessity to postulate changes in auxin metabolism to account for various growth responses to changed environment.

A session on regulators was of general interest, and included papers on light quality and periodicity, on the regulation of enzyme synthesis, photosynthesis and nuclear activity by hormones and on the mode of action of herbicides.

Two sessions were held on metabolism, covering a wide range of research interests. A growing interest in the phenolic substances in plants was evidenced by a group of papers from the Halifax, Nova Scotia, laboratories of the National Research Council under the direction of Dr. A. C. Neish and Dr. G. H. N. Towers. These included very interesting work on the pathways of lignin biosynthesis and the interrelations of soluble and insoluble derivatives of the many C_6–C_1 and C_6–C_3 phenolic acids found in plants. Other papers included biosynthetic investigations on indoles, carbohydrates, phosphatides, alkaloids and chlorophylls. A number of papers were presented on various problems in plant metabolism, including organic acid metabolism, respiration, frost hardiness, and the influence of seasonal or environmental factors on plant metabolism.

A session was held on cell biology, which included cytological and cyto-physiological investigations on tissue cultures of Jerusalem artichoke and oat coleoptiles, originating from the Carleton University, Ottawa, laboratories of Dr. G. Setterfield and Dr. F. Wightman. It was shown that a number of synthetic auxins which promote cell expansion also promote cell division. Papers were presented on control mechanisms of amino-acid synthesis, on chloroplast bleaching in *Euglena*, and on histochemical tests. Dr. Nelson's group from Queen's University presented work on the effect of auxin in controlling cellular permeability, and on the electro-osmotic transport of sugars labelled with carbon-14 in *Nitella* cells.

The non-scientific event of outstanding significance at the meetings was the holding of a banquet in honour of Prof. D. L. Bailey (Botany Department, University of Toronto). Dr. Bailey is retiring from the editorship of the *Canadian Journal of Botany*, the official journal of the Society, after a number of years of outstanding service in which he has maintained the *Journal* at the highest possible standard. Special guests at the banquet included

Dr. Leo Marion editor-in-chief of the *Canadian Research Journals*, and Dr. Pauline Snure, manager of the editorial office.

At the business meeting it was decided that next year's annual meeting will be held in early June at the University of New Brunswick, Fredericton, New Brunswick. Dr. G. Setterfield (Carleton University, Ottawa) was elected president of the Society, Dr. A. R. A. Taylor (University of New Brunswick) was elected vice-president, and Dr. R. G. S. Bidwell (University of Toronto) was re-elected secretary–treasurer. Other officers of the Society are Dr. M. Shaw (University of Saskatchewan) (past president), Dr. M. Cailloux (Université de Montréal) (eastern director) and Dr. Mary Spencer (University of Alberta) (western director).

R. G. S. BIDWELL

UNIVERSITY LIBRARY SERVICES

A MEMORANDUM outlining the responsibilities and functions of university libraries has been submitted by the librarians of Britain's new universities to the Committee on Libraries of the University Grants Committee. It sets forth, first, the function of the university library; next, the level and scope of acquisitions; the need for undergraduate provision; and then discusses problems of building and accommodation and of library co-operation.

The memorandum begins by insisting that the first function of a university library is to support the teaching and research of the institution it serves, but that it also has a duty to the community of learning at large and access to its resources should be available to all serious students who need to consult them. As research grows and a larger proportion of the population receives a higher education, such extra-mural activities are likely to grow in importance, The memorandum insists that librarians must play a much more positive part in exploiting the books in their libraries, both by information work and by giving instruction and guidance to students and research workers. Dealing with the level and scope of acquisitions, it indicates the magnitude and urgency of the situation confronting the new university librarians, and the acquisition of books and periodicals is seen as still the most important task which the university library must perform.

The library provision varies widely among the existing universities in Britain, and the inequality has increased rather than diminished since 1945. Only Cambridge, Oxford and London provide really comprehensive collections for research in Britain, although in the United States several university libraries have doubled or more than doubled their size since 1945. The rise in income of British university libraries during the past 15 years has been almost totally absorbed by the increase in publishing and the steady rise in prices. The memorandum suggests that the new universities should aim at collecting 250,000 volumes apiece during their first ten years, excluding multiple copies of undergraduate texts. Substantial capital grants will be required. The minimum cost of provision of periodicals in mathematical, physical, chemical and biological sciences may approach some £10,000 a year, although two-thirds of Britain's present universities spend less than this figure on periodicals and one-third spend less than £5,000.

The need for the student to have the use of a comprehensive library is emphasized by the memorandum, and it is pointed out that multiple provision of text-books makes possible a better lending service while provision of a reference copy ensures that both students and other users of the library can usually obtain access to certain books. The setting-up of separate undergraduate libraries in new universities is not favoured, but it is suggested that duplication of minimum book needs for each undergraduate course should be on a scale depending on the number of students involved. Funds available to university libraries, at least outside Oxford and Cambridge, are quite inadequate to provide multiple copies on the scale necessary, and students in some subjects cannot reasonably be expected to provide themselves with more than a small number of the many books they will need to consult in the course of three years. Grants are therefore needed for multiple book provision.

On buildings and accommodation, the memorandum points out that the new universities are in a position to take immediate advantage of the developments in university planning, particularly in the United States, since the Second World War and of recent developments in fast building techniques. University teaching methods will influence planning and the typical new library is likely to be designed on a flexible plan, with large open floors in which readers are placed close to blocks of bookshelves grouped according to subject. More generous space allowances are required and variety of provision for readers is essential. Some experiments in extended hours of opening are already being made. On co-operative storage and technical developments, the memorandum affirms the intention of the new universities to build up their libraries on the principle that the university library must possess within its own walls copies of almost everything required by its members for the promotion of their studies and the advancement of learning. However, it is believed that a proper policy for the withdrawal of obsolescent material should also be admitted. A national co-operative scheme now ensures that a copy of every recent worth-while British book is available for loan somewhere, but the universities still need to buy their own copies to cover their own requirements, and the possible advantages of a co-operative approach are regarded as worthy of investigation. Some advantage might accrue in the acquisition of periodicals from the co-operative coverage of all new titles of academic interest. The reductions available when a number of libraries purchase specially reproduced copies of out-of-print books are large enough to justify an attempt to set up a co-operative non-profit-making organization scheme. Any scheme for co-operative storage must provide for bibliographical care and maintenance so that material is available quickly when needed. The most immediate help in co-operative work that could be given is the provision of more funds for the important comprehensive catalogues, in particular, the national catalogues in the National Central Library. It is submitted in the memorandum that there is a strong case for amending the copyright regulations in the interests of efficiency and economy in learned institutions so as to facilitate the reproduction of copies from telefacsimiles and the request of photocopies by 'Telex'. There are difficulties in acquisition and in the use of microforms which militate against any substantial savings for libraries. However, the amount of bulky and little-used material kept in microform is likely to increase and to offer some economy in storage costs. More information is needed on many aspects of library organization, and none of the existing organizations is capable of undertaking this work. The memorandum suggests that there is scope for a small library development agency, the staff of which might both collect information and assist the co-operation of academic libraries.

Copies of the memorandum can be obtained from Mr. P. E. Tucker, librarian, the University of Warwick, Coventry, Warwicks.

RESEARCH IN TEXTILES, COLOUR CHEMISTRY AND DYEING

THE eighty-ninth report to the Worshipful Company of Clothworkers of the City of London of the Advisory Committee on the Departments of Textile Industries and Colour Chemistry and Dyeing in the University of Leeds* covers the session 1962–63. During the session there were 400 students in the Department of Textile Industries, of whom 96 were graduates reading for higher degrees or diplomas, compared with 12·5 per cent such students for the University as a whole. Twenty-eight students were awarded Bachelor degrees and 27 gained diplomas.

In textile physics, a method was devised for determining the contribution of the relevant molecular configuration to the overall crystallinity from the dimensional change of the microfibrils measured in electron micrographs of the transverse sections of wool fibres: the results confirmed the view that an intermediate molecular phase was involved in the α–β transformation. Work in textile chemistry during the session was concerned with attempts to devise methods for the continuous curling of worsted and mohair yarn, for lustring all-wool fabrics, and for imparting permanent creases and pleats to all-wool fabrics under simpler conditions. Work was also continued on the prevention of heat discoloration of wool textiles, and the properties of the by-products of the fleece were further examined. The fundamental investigation of traveller burning was extended and a complete analysis made of the position of the traveller during flight. A novel method of cleaning wool which might eliminate the card and produce wool of much more even fibre length is being examined. An extensive programme of work to explain the mechanical behaviour of cloths in terms of yarn properties and cloth geometry yielded some useful results. In textile technology the effect of the arc of contact in a carding machine on the efficiency of the carding process was investigated, and, in worsted spinning, attention was directed to the drawing and spinning of coloured tops. An investigation was completed in the production and properties of nylon and 'Terylene', false-twist mixture yarns. Work in textile finishing covered the chemistry and practice of textile processing with particular attention to the flame-proofing of textiles and the reactivity and properties of nylon- and wool-setting operations.

In the Department of Colour Chemistry and Dyeing, there were 42 undergraduates during the eighty-fourth session and 14 graduates working for research degrees.

In research, a preliminary study of the mechanism and formation of dioxazine dyes was completed and the reactions of 9,10-benzo*meso*-benzanthrone with nucleophilic reagents were examined, as well as the acetylation of 1,1-dinaphthyl and perylene.

Research continued on the measurement of the vapour pressure of disperse dye crystals, and investigations were made of the behaviour of dispersed dye particles in the dye bath, of the ring dyeing of circular filaments of nylon, 'Terylene' and 'Courtelle', and of the important technical process of rosination in the manufacture of azo pigments. Investigations of the treatment of wool in various media on its load-extension and setting characteristics were completed, as well as others on the solvent-assisted dyeing of nylon 66. An investigation into factors influencing the strength of the dye fibre bond formed by reacting halogeno triazinyl dyes and cellulose was commenced.

Lists of departmental publications during the year are appended to both departmental reports.

---

THE ZOOLOGICAL SOCIETY OF LONDON

THE 135th annual report of the Council of the Zoological Society of London* shows that, at the end of 1963, there were 3,526 Fellows and 1,448 Associates. Although public attendances at the Society's Zoological Gardens improved a little in the year, the 1963 figure was still some 65,000 below the average of the previous seven years. This recovery did not extend to Whipsnade, where attendances, at 616,000, were below even the 1962 level. Since the Society must rely on substantial annual surpluses, and since the bulk of income must still come from the public, the Council has commissioned a firm of consultants to report on the Society's revenue-earning activities and to suggest ways by which they can be improved.

To further its policy that zoos should, wherever possible, take positive action to ensure the survival of endangered species, the Council sent the female Arabian oryx, which has been in the collection since 1958, on loan to the Phoenix Zoo, Arizona, where a breeding herd of captive oryxes was being established. This herd consists of two adult male and three adult female oryxes, two males and one female having been captured by the expedition sent to the Aden Protectorate by the Fauna Preservation Society and another female presented by H. E. Sheikh Jabir Abdullah Al Sabah of Kuwait. The first offspring, a male, was born at Phoenix Zoo in October.

There have been several rare births in the Gardens during the year. From the point of view of conservation, probably the most important birth was that of a second orang-utan to the breeding pair at Regent's Park, 'Toli' and 'Charlie'. This young male is being successfully reared by its mother, while its elder sister (born in 1961) continues to thrive with a chimpanzee as a companion. During 1963, the upper section of the stables in the Children's Zoo at Regent's Park was completely remodelled as a small pilot experiment for the nocturnal section of the new Small Mammal House. Here small nocturnal mammals are being kept under various lighting conditions in an attempt to find out the best way of reversing their daily rhythm. The tests have already proved successful and, when they are completed, the building will be opened as a temporary display until the completion of the new Small Mammal House. Animals housed there include bush-babies, lorises, pottos, douroucoulis, mouse lemurs and giant flying squirrels.

The report contains some outstanding photographs recording the births of various animals at Regent's Park and Whipsnade.

EXCITATION OF CEREBELLAR PURKINJE CELLS BY THE CLIMBING FIBRES

By Sir JOHN ECCLES, F.R.S., R. LLINAS and K. SASAKI

Department of Physiology, Australian National University, Canberra

IN 1888 Cajal (ref. 1) discovered a most remarkable synaptic structure in which single afferent fibres were uniquely related to single Purkinje cells by synaptic contacts of extraordinary extent and intimacy. As illustrated in Fig. 1*A*, each so-called climbing fibre (*CF*) traverses the granular layer of the cerebellar cortex up to the soma of a Purkinje cell (*P*) and enters into close contact with the trunk of the dendritic tree at its origin from the soma, thereafter branching profusely so that the primary and secondary dendritic branches are entwined by climbing fibrils. There are descriptions of climbing fibres that branch to entwine dendrites of two or even more Purkinje cells[2]; nevertheless in the great majority there is the one-to-one relationship described by Cajal[1]. With the electron microscope[3] it can be seen that, as the climbing fibre twines round the first and second order dendrites of a Purkinje cell, it makes numerous synaptic contacts that have the features of Gray type 1. These contacts are with the dendritic shafts and not with dendritic spines, which invariably are the sites for the synapses (also Gray type 1) made by the parallel fibres[3-7].

The origin of the climbing fibres was controversial until careful degenerative investigations[8] showed that the great majority arose from the inferior olivary nucleus in the medulla, which is unique in that it does not contribute at all to the only other type of cerebellar afferent fibre, the so-called mossy fibres (Fig. 1*A*, *MF*). Experimentally, therefore, it should be possible to stimulate climbing fibres selectively by means of an electrode inserted into the inferior olive. Dow[9] and Jansen[10] found that stimulation of the inferior olive produced a complex potential change (often positive-negative) in most areas of the cerebellar cortex, especially contralaterally, and the sensitivity to anoxia indicated the synaptic generation of this potential. It will here be shown that the potentials synaptically generated in Purkinje cells by stimulation of the inferior olive have precisely the characteristics that would be expected for the synaptic action of impulses in climbing fibres.

Fig. 1*A* illustrates diagrammatically the experimental arrangements which in general resemble those already described[11]. In a small segment of the anterior lobe of the cerebellar vermis there are indicated several somata of Purkinje cells, only one (*P*) being shown with dendrites and the associated climbing fibre (*CF*). Antidromic stimulation of the Purkinje cell was effected by means of a concentric needle electrode (*ANT. STIM.*) in the white matter adjacent to the fastigial nucleus, but, as indicated, such stimulation would also be likely to excite climbing fibres (*CF*) and mossy fibres (*MF*) as well as Purkinje cell axons (*PA*). By contrast the other concentric electrode (*I.O. STIM.*) in the inferior olivary nucleus should excite only climbing fibres. A surface bipolar electrode (*LOC. STIM.*) was used for local stimulation of the parallel fibres, which are the axons of granule cells (*G*). The insertion of the potassium citrate-filled microelectrode (about 10 MΩ) is indicated. The animals (cats) were anæsthetized by pentobarbital sodium and paralysed by 'Flaxedil'. Conventional procedures were used in order to control the movements of the cerebellum: pneumothorax with artificial ventilation, and coverage of the exposed cerebellar cortex by an agar gel.

In Fig. 1*B* the very early diphasic spike potential (positive-negative with 0·6 msec latency) evoked by stimulation through the *ANT.* electrode shows that the microelectrode was in very close proximity to a Purkinje cell responding antidromically to this stimulus. The second spike (about 3 msec latency) would be evoked synaptically, presumably by the following pathway: the mossy fibres stimulated as they pass by the *ANT.* electrode, thence to the granule cells and their parallel fibres, and so to the Purkinje cells. Correspondingly, in the initial response of Fig. 1*G*, direct stimulation of the parallel fibres (*LOC. STIM.* in Fig. 1*A*) evoked a spike potential with a latency of almost 4 msec. In *C* the stimulus to the inferior olive (*I.O.*) was just at threshold for evoking a response of this same Purkinje cell, there being three superimposed traces, one below threshold and two above that each evoked 4 or 5 spike potentials, the traces of the first two spikes being superimposed. The details of this complex spike response are better seen in the single trace of *D*. The latency of the first spike was about 11 msec and there was a considerable diminution in the size of the later spikes, which presumably is attributable to the maintained depolarization of the cell. Further increase in the *I.O.* stimulation did not cause any addition to the response in *C* and *D*, which was thus strictly all-or-nothing. Since stimulation of parallel fibres produces a very large inhibitory postsynaptic potential (*IPSP*) via basket cells[11], it would be expected to inhibit the response evoked by the *I.O.* stimulation, as is illustrated in Fig. 1*E*–*G*. However, the first spike could not be suppressed even at the optimal interval of about 10 msec (*E*) after the

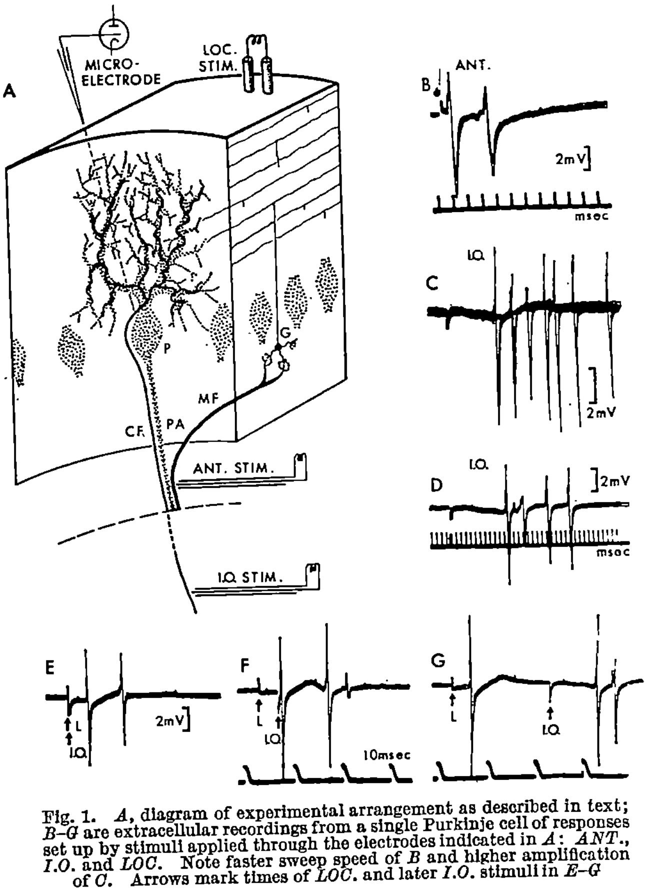

Fig. 1. *A*, diagram of experimental arrangement as described in text; *B*–*G* are extracellular recordings from a single Purkinje cell of responses set up by stimuli applied through the electrodes indicated in *A*: *ANT.*, *I.O.* and *LOC.* Note faster sweep speed of *B* and higher amplification of *C*. Arrows mark times of *LOC.* and later *I.O.* stimuli in *E*–*G*

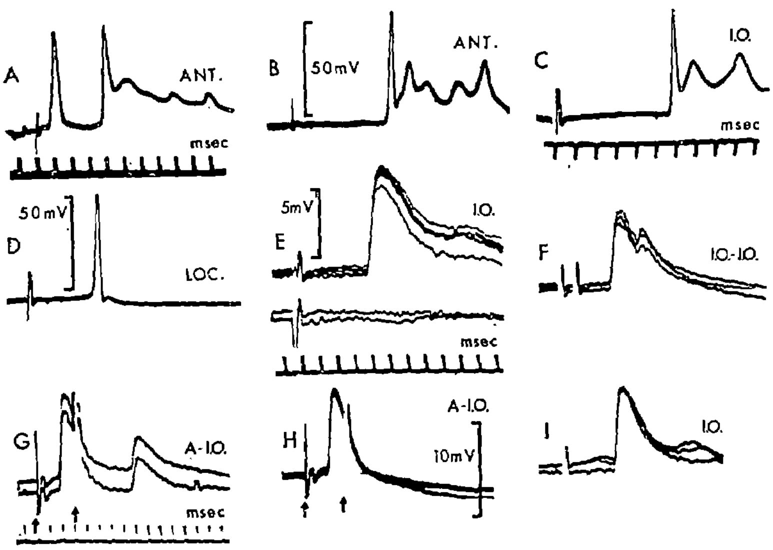

Fig. 2. Intracellular recordings from three Purkinje cells. In two, *A* and *B–D*, the membrane potential was −50 mV and the spike potentials 50–60 mV. *A* and *B* are responses to *ANT*. stimulation, *C* to *I.O.* and *D* to *LOC.* stimulation. All are at the same amplification, and *B–D* at same sweep speed. The other cell (*E–I*) had such a low membrane potential, declining from −40 mV, that there were only *EPSP*'s uncomplicated by spike potentials. *E* was at higher amplification and faster sweep than *F–I*, and illustrates the all-or-nothing character of the *EPSP*, the two lower traces with zero response being evoked by a slightly weaker stimulus. *F* is the double *EPSP* evoked by double *I.O.* stimulation at the shortest effective interval. In *G* similarly there is the double *EPSP* response at the shortest *ANT.-I.O.* stimulus interval, there being failure of the second stimulus at a very slightly shorter interval (*H*). *I* shows control *EPSP* to *I.O.* stimulation alone

local (*L*) stimulation, which shows how powerful is the excitatory action from the inferior olive. Progressive recovery is seen at longer intervals (*F*, *G*), but full recovery did not occur until at least 100 msec after the *L* stimulus, which corresponds to the duration of the *IPSP* recorded intracellularly[11]. It can be concluded that in Fig. 1*C–G* the stimulation of a single fibre in the inferior olive resulted in an extremely powerful synaptic excitation of that Purkinje cell. Similar observations have been made on the large number of Purkinje cells that were activated by an *I.O.* stimulation.

Intracellular recording (Fig. 2) gives further information on the extraordinary power of synaptic depolarization that is always exerted by a single impulse from the inferior olive. In Fig. 2*D* stimulation of the parallel fibres (*L* stimulus) typically evoked a single spike discharge (latency 3·2 msec) followed by the prolonged hyperpolarization of the *IPSP*. With *I.O.* stimulation (*C*) there was an initial spike (latency 5·8 msec) followed by two large slow depolarizing waves, a response that was almost exactly reproduced in four successive tests, and was also observed as a spontaneous response. Fig. 2*B* also shows that a similar response was produced by stimulation through the *ANT*. electrode, but with a briefer latency (4·7 msec). Evidently this electrode was unfavourably placed for stimulating the axon of the impaled Purkinje cell, which was affected solely by the excitation of the same fibre that was excited by the *I.O.* stimulus. The *ANT*. electrode was more favourably placed in another experiment (Fig. 2*A*), where the initial antidromic spike potential (latency 0·7 msec) was followed 3·1 msec later by a spike potential and the subsequent complex depolarizing potential resembling that of Fig. 2*B*.

That the *ANT*. stimulus can synaptically excite a Purkinje cell by setting up an impulse in a nerve fibre from the inferior olive is shown in the series of Fig. 2*F–G* from another Purkinje cell that was so depolarized by the microelectrode impalement that no spike potentials could be generated. In *E* the *I.O.* stimulation is seen to generate in an all-or-nothing manner a depolarization (*EPSP*) in the Purkinje cell with a latency of 4·1 msec. A similar all-or-nothing *EPSP*, but with a latency of 1·9 msec, was generated by the *ANT*. stimulus. In *G–H* the *ANT*. stimulus preceded the *I.O* stimulus and the least stimulus interval a which the latter stimulus evoked an *EPSI* was 3·2 msec (*G*), whereas with two *I.O* stimuli the least stimulus interval was 1· msec (*F*). It can be concluded that botl stimuli were exciting the same nerve fibr and that the propagation time to the inferio olive of the impulse evoked by the *ANT* stimulus was 2·1 msec (3·2–1·1), which is i good agreement with the propagation tim in the reverse direction, 2·2 msec (4·1–1·9) that is given by the latency differential fo the *I.O.*- and *ANT*.-evoked *EPSP*'s. Simila experimental tests have been applied t many other cases where the *ANT*. and *I.C* stimul evoked the same responses of Purkinje cell, and always there were com parable results. From the conduction time so measured for the impulse propagatior mean conduction velocities of approxim ately 10–15 m/sec have been calculatec which is in good agreement with the dia meter of rather less than 3μ that is observe for the majority of olivo-cerebellar fibres[1]

It can be concluded that fibres excite in the inferior olive have a very powerfu synaptic excitatory action on single Pur kinje cells, exactly as would be expecte for the massive synaptic relationship ob served histologically for the climbin fibre, which is in special agreement wit Szentágothai and Rajkovits[8]. Furthermore, this actio has the expected uniqueness in that we have so far neve observed evidence of convergence of two such fibres on t a Purkinje cell. The extracellular records of Fig. 1*C–* show the intense repetitive discharge that an impuls in a climbing fibre evokes from a normal Purkinje cel so much so that it cannot be completely suppressed eve by the powerful inhibition produced by basket cells[1] In Fig. 2*A–C* the depolarizing waves after the first spik probably are caused in part by electrotonic spread fro spikes generated in the Purkinje cell dendrites th failed to propagate into the soma, presumably because its excessive depolarization, but impulses generated the initial segment (*IS*) of the axon would also contribut For example, the second spike potential in Fig. 1 probably is an *IS* spike.

Responses resembling those of Fig. 2*A*, *B* were observe by Granit and Phillips[13] also in response to juxt fastigial stimulation and were called by them 'inactivati responses' because of the suppression of spike generati by the depolarization, just as in Fig. 2*A*, *B*. Spontaneo inactivation responses were also observed by them. W would attribute all these responses to the very powerf synaptic excitatory actions of impulses in the climbi fibres because they can be duplicated by stimuli appli to the inferior olive. It can be predicted that this ve specific and powerful activation of Purkinje cells has most significant function in the co-ordination muscles.

RECOVERY FOLLOWING X-IRRADIATION OF SYNCHRONIZED CHINESE HAMSTER CELLS

By DR. W. K. SINCLAIR and R. A. MORTON

Division of Biological and Medical Research, Argonne National Laboratory, Argonne, Illinois

AN implication of the shape of threshold-type radiation survival curves (called "Type C" by Gunter and Kohn[1]) is that damage must be accumulated before the cell is killed. Elkind and Sutton[2] used fractionated doses of X-radiation to investigate the heritability of this accumulated damage among surviving cells. They found their results to be consistent with repair of sub-lethal damage before the first division after exposure. Similar observations have been reported in other mammalian cell lines[3,4], in *in vivo* mammalian investigations[5,6] and also in plant cells[7]. The phenomenon is, therefore, rather general and may, in fact, always exist whenever thresholds or shoulders occur in survival curves.

The interpretation of the kinetics of the recovery process is complicated when asynchronous populations of cells are used. It has recently been shown by several investigators that the X-radiation sensitivity of mammalian cells varies with age of the cell[8], that is, with time in the cell cycle from one division to the next[9–12]; consequently, after an asynchronous population is exposed to X-rays, the age-density distribution[8] of survivors is different from that of an unirradiated exponentially growing population. Subsequent progression of surviving cells through different sensitivity states leads to changes in the response to a second or test dose which may obscure the effects of a repair process, or possibly even give the appearance of such a repair process when none exists. Kallman[13] has described a model in which variations in sensitivity with cell age are responsible for oscillations in the form of the response of asynchronous cells to two separated X-ray doses and in which no intracellular repair process is invoked. Although various arguments and some recent experimental evidence by Elkind and others[14,15] and by Berry and Oliver[16] support the hypothesis of intracellular repair, the fact is that under normal conditions, only when the exponential age-density distribution is restored can the recovery or repair process be investigated free of the effects of cell progression through different sensitivity states. The interpretation of the response of surviving cells in the transient period following a first exposure is further complicated by our own observation[17,18] that, in Chinese hamster cells, variations in X-ray sensitivity with cell age are mainly due to alterations in the threshold region of the survival curve, that is, that part of the dose-effect curve intimately concerned with sub-lethal damage. We have attempted to clarify the process of repair of sub-lethal damage by studying the responses of synchronized populations of Chinese hamster cells to two doses separated by various time intervals.

Chinese hamster cells derived from the *V*79 clone and grown *in vitro* have been synchronized by a selection procedure involving a brief cold shock, re-incubation at 37° C for a period and then controlled agitation under gentle trypsinization[11]. Cells at or near mitosis are obtained. On subsequent recultivation, the cells form 1 or 2 cell 'colonies' during the first cycle of synchronous growth. By various tests, which include mitotic index, cell-size distributions, growth and pulse labelling with tritiated thymidine, these populations have been shown to be quite well synchronized[18].

The response of these cells after a single X-ray dose has been discussed in earlier reports[11,18] and was obtained by exposing synchronized cells incubated for different lengths of time at 37° C to a given dose of X-rays from a General Electric Maxitron machine 250 kVp, 0·9 mm copper half-value layer, at an exposure rate of 110 r./min (absorbed dose = 0·945 rad/r.). The fractionated exposures were conducted by removing an entire set of plates at a given time after re-incubation (during the first cycle) and exposing to the first dose. The plates were then restored to the incubator and removed at intervals thereafter to receive the second dose. Final incubation for 10–12 days results in visible colonies, each representing a survivor. For each exposure, the plates were out of the incubator (that is, at ~ 25° C) for about 15–30 min. This length of time at room temperature may have a small effect on survival, but the degree of synchrony, as judged by plates pulse-labelled with tritiated thymidine after exposure (Fig. 2), is substantially unaffected.

Recovery of S Phase Cells. Fig. 1 shows the survival following a single dose of 660 rads at various times (curve 1*A*), 1,320 rads at these times (curve 1*B*) and a two-dose response for 660 rads delivered at 10 h (when most of the cells are in the *S* phase) followed by a further 660 rads at intervals thereafter (curve 1*C*). The survival after two separated doses of 660 rads (Fig. 1*C*) quickly rises above that for the same total single dose, 1,320 rads (Fig. 1*B*), as the interval between the two doses increases. (The first point on Fig. 1*C* should lie exactly on Fig. 1*B*; it is slightly below only because the two sets of plates were not handled exactly alike.) Since cells of age 10 h in this population (Fig. 1*A* and 1*B*) are near their maximum resistance and moving toward a more sensitive state, the first increase in Fig. 1*C* can only be the result of recovery from the first dose. Beyond the first maximum, the survival after the fractionated dose (Fig. 1*C*) follows a very similar pattern to that after the same single total dose (Fig. 1*B*) but displaced toward later times (by about 2·5–4 h) and higher survival levels. The higher survival level indicates that the recovery is permanent and not transient in character.

Degree of Recovery in S Phase Cells. In the same experiment, cells were pulse-labelled with tritiated thymidine (15 min, 0·4 μc./ml., 3 c./mM). Fig. 2*A* shows that at 10 h 80 per cent of the cells were still synthesizing DNA. Since *S* cells are quite resistant (Fig. 1*A* and 1*B*)[11,18] after the first dose (of a two-dose pair) given at 10 h, most of the survivors will be *S* phase cells. Thus the response to two doses shown in Fig. 1*C* is for primarily *S* phase cells. Fig. 2*B* shows the percentage of cells labelled versus time for a population given 660 rads at 10 h, but since only 20 per cent of single cells would survive this dose (Fig. 1*A* and equation (1)) this curve refers mainly to non-colony forming cells. However, Fig. 2*B* indicates that the irradiated population retains most of its synchrony. The principal effect of the exposure was a delay of about 2·5–4 h, depending on where the two curves were compared. This is consistent with the delay observed in the survival data of Fig. 1 (compare curves 1*B* and 1*C*) which is to be expected if the rate of progression of survivors and non-survivors is the same[19].

The increase in survival after two separated doses (Fig. 1*C*) may be evaluated quantitatively by comparing the response to the second dose of first-dose survivors, with the response of single, unirradiated cells. Such a comparison is possible, if, as we have seen, cells after a

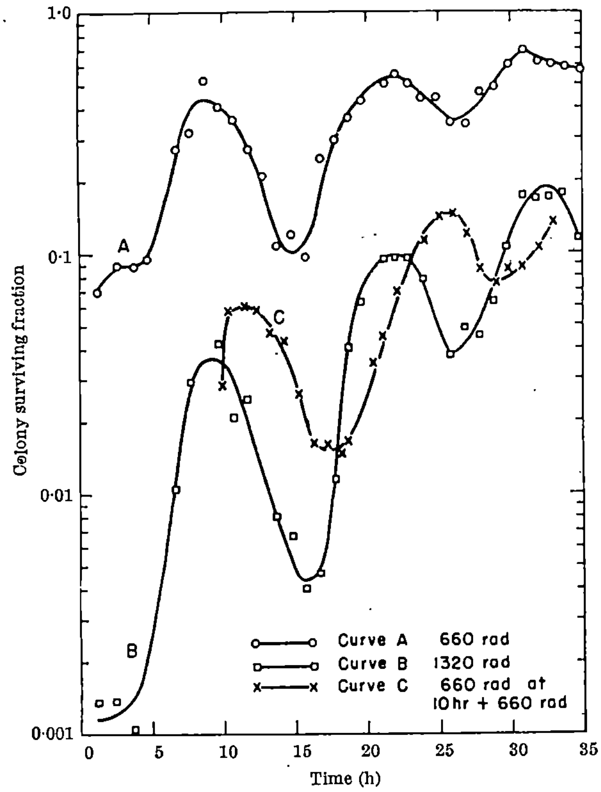

Fig. 1. Colony survival of synchronized hamster cells after 660 rads at intervals of time after incubation (curve *A*), 1,320 rads at intervals (curve *B*), and 660 rads at 10 h followed by 660 rads at further intervals (curve *C*). The first generation cycle ends at about 15 h and the second at about 26 h

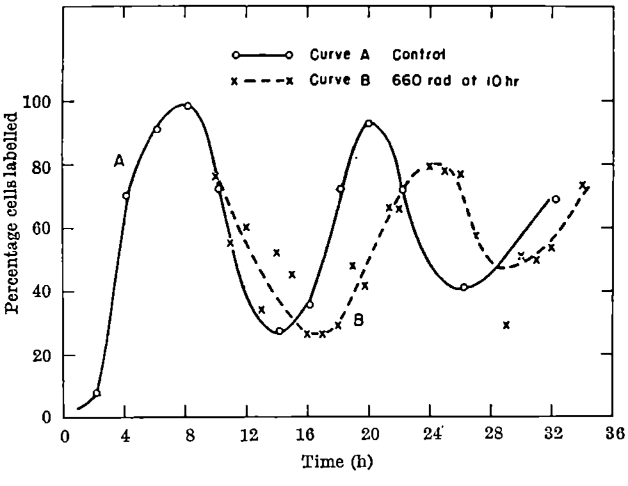

Fig. 2. Percentage of cells labelled with a pulse of tritiated thymidine (0·4 μc./ml. for 15 min) against time after incubation of the synchronized population. Unirradiated cells (curve *A*); cells after 660 rads at 10 h (curve *B*)

first dose are still quite well synchronized and if the initial distribution of cells per colony is known. In Fig. 3*A*, the average number of cells per colony for this experiment, $\bar{N}(t)$, is shown as a function of time. The single cell survival, $S(t)$, after 660 rads, shown in Fig. 4*A*, is then found from the colony survival after 660 rads, $f(t)$, (Fig. 1*A*) by means of the following equation[18]:

$$S(t) = 1 - [1 - f(t)]^{1/\bar{N}(t)} \qquad (1)$$

Values of $f(t)$ were taken from Fig. 1*A*.

Strictly speaking, $\bar{N}(t)$ should be that for viable cells only, and because the plating efficiency of these cells is not 100 per cent, $\bar{N}(t)$ shown in Fig. 3*A* includes both viable and inviable cells. The error in using the observed values for $\bar{N}(t)$ is not large, however, and has been discussed elsewhere[18]. The effect of a second 660 rads on survivors of a first dose of 660 rads at 10 h was found as follows. The observed colony survival after two doses, Fig. 1*C*, was divided by the fraction of colonies surviving a single dose of 660 rads at 10 h ($\sim$ 0·40 in this case, Fig. 1*A*). This gave the fractional survival to the second dose as a function of the time-interval between doses. Unfortunately, the survivors were not quite single cells, even initially, but the average multiplicity $\bar{N}_s$ of these survivors was calculated using equation (2) for $\bar{N}_s$ at 10 h:

$$\bar{N}_s\,(10\text{ h}) = \frac{S\,(10\text{ h})\,.\,\bar{N}\,(10\text{ h})\,.\,N_0}{f\,(10\text{ h})\,.\,N_0} \qquad (2)$$

where N_0 = total colonies that would form on an unirradiated plate. N_0 is constant, but in any event it cancels. $\bar{N}_s(t)$ at any later time t may then be plotted as in Fig. 3*B* assuming that $\bar{N}_s(t)$ follows a pattern just like that of $\bar{N}(t)$ but displaced from it by 2·8 h (Figs. 1 and 2). Equation 1 with $\bar{N}_s(t)$ substituted for $\bar{N}(t)$ was then used to calculate the single-cell survival after the second 660 rads (Fig. 4*B*). To summarize, Fig. 4*A* represents the single-cell survival after 660 rads as a function of cell age throughout 2·5 division cycles. Fig. 4*B* represents the survival after a second dose of 660 rads, for single-cell survivors given a first dose of 660 rads at 10 h. It may be seen from Fig. 4 that: (1) desynchronization of the population with time is evident in both curves; (2) the initial increase in the response to a second dose with time (Figs. 1*C* and 4*B*) is consistent with repair of sub-lethal damage; (3) concurrent with this repair, the survivors after 660 rads progress

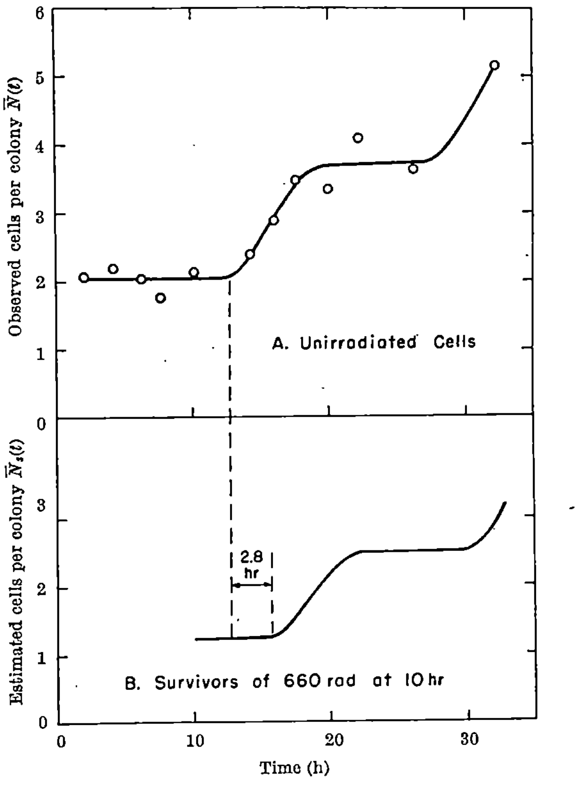

Fig. 3. Cells per colony observed by counting stained unirradiated cells (curve *A*). Cells per colony estimated for the survivors of 660 rads at 10 h (curve *B*) (see text)

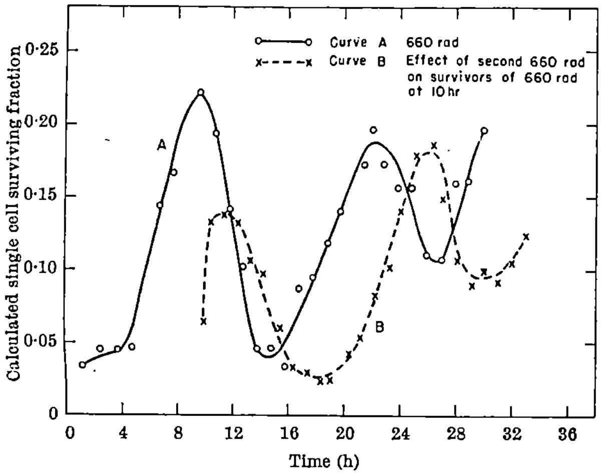

Fig. 4. Calculated age-response of single synchronized hamster cells to 660 rads. Curve *A*, previously unirradiated cells; curve *B*, cells which survived a preliminary 660 rads at 10 h

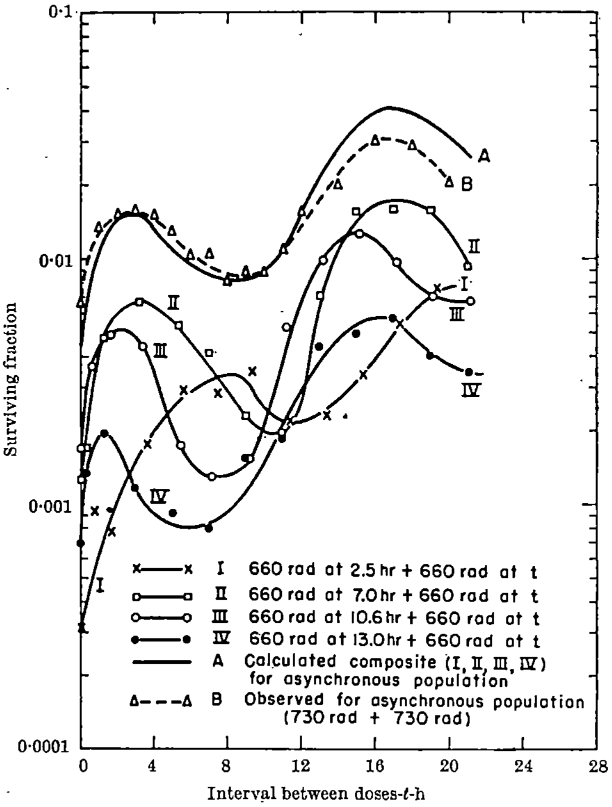

Fig. 5. The response of an asynchronous population of single cells to two doses of 660 rads separated by different time intervals. Curve *A*, estimated from the sum of four components I, II, III and IV receiving first doses at different cell ages, 2·5 h, 7·0 h, 10·6 h and 13·0 h, respectively. Curve *B*, experimental data for an asynchronous population exposed to 730 rads + 730 rads. Curve *B* had the same survival-level as curve *A* at the peak response, that is, at an interval of about 2·5 h between doses

through the cycle with a gradually increasing delay (that is, a decrease in rate); (4) apart from delay, Fig. 4*B* exhibits a pattern so similar to Fig. 4*A* after the first division that we conclude repair is complete, that is, the response of survivors to the first dose appears eventually to be just like that of unirradiated cells, at least at these dose-levels.

Recovery of Cells not in the S Phase. The foregoing results indicate that cells in the *S* phase are capable of complete sub-lethal repair, in so far as colony formation is concerned, within a relatively short time. It is possible, however, that the recovery process may be age dependent, that is, cells in the pre-DNA synthetic period G_1 or post-DNA synthetic period G_2 may not be able to repair sub-lethal damage as effectively or perhaps not at all. There are several reasons why these phases are much more difficult to investigate. First, if the amount of sub-lethal damage is indicated by the magnitude of the shoulder, the effect one might hope to see is smaller because G_1 and G_2 cells have survival curves with much smaller shoulders than do *S* cells[17,18]. Secondly, our synchronized cell population is never entirely free of some *S* cells at any cell age. For example, at 1–2 h in G_1 we may have about 5–10 per cent (Fig. 2) of the cells synthesizing DNA (perhaps because some cells have an extremely short G_1 or perhaps because the labelled cells represent a small fraction of non-synchronized interphase cells). Since cells in *S* are more resistant, their percentage is increased in the survivors of the first dose and recovery among these *S* cells can obscure the smaller recovery to be expected in the remaining G_1 cells. This situation is accentuated in G_2 where the fraction of cells still in *S* is higher. Thirdly, G_1 cells are progressing toward a state of greater resistance and thus a rise in survival due to recovery is less easy to distinguish. Cell progression operates more in our favour for G_2 cells, however. For these reasons, two-dose studies in Chinese hamster cells of the type described here yield information primarily about the most resistant component (that is, cells in *S*).

Response of an Asynchronous Population. In spite of these limitations concerning the specificity of recovery as a function of cell phase (G_1, G_2 or *S*), the two-dose response at different times in the synchronous population may represent an appropriate average for the purpose of analysing the response of asynchronous cells. Fractionation experiments at various cell ages in the synchronized population may, therefore, provide useful information concerning the form of the response to be expected for asynchronous cell populations.

A two-dose experiment was conducted in which first doses of 660 rads were delivered at 2·5 h, 7·0 h, 10·6 h, and 13·0 h followed by second doses of 660 rads at intervals of up to 20 h after the first dose. Other samples were exposed to single doses of 660 rads and 1,320 rads, respectively. An initial rise in the two-dose response (similar to that shown in Fig. 1*C*) occurred at all four cell ages but was greatest (as expected) for 7·0 h and 10·6 h cells. The data obtained were used to construct the response to be expected from an asynchronous population. The calculation, in outline, was as follows:

After an asynchronous log-phase population is exposed to a first dose of 660 rads, the age distribution of survivors was found by multiplying the age-response of single cells after 660 rads (for example, Fig. 4*A*) by the appropriate age-density distribution[20]. The curve obtained for the first-generation cycle was divided into four regions (I, 0–5 h; II, 5–9 h; III, 9–12·5 h; IV, 12·5–16 h) and the area under each multiplied by the effect of a second dose of 660 rads for first doses at 2·5 h, 7·0 h, 10·6 h, and 13·0 h, respectively. This procedure yielded the contribution of each of the four age regions to the overall two-dose response of asynchronous, log-phase cells as shown by curves I, II, III, and IV in Fig. 5. The survival response to be expected for the entire asynchronous population was then obtained by the addition of these four curves (Fig. 5*A*). For comparison purposes, the results of an actual experiment on an asynchronous population are included (Fig. 5*B*). Although slightly different dose fractions were used, this experiment yielded about the same survival at the maximum (that is, at ~2·5 h) and the form of the response is not strongly dose dependent[8]. In spite of minor differences, the general features of Fig. 5*A* and Fig. 5*B* are the same.

The following conclusions may be drawn from these investigations.

(1) Chinese hamster cells in the *S* period which survive a first dose of X-radiation repair fully the sub-lethal damage incurred, as defined by their ability to form colonies when challenged with a second dose. For a more comprehensive study of these effects at different dose-levels, full survival curves need to be obtained. (2) The repair process is rapid and may be complete in about 2–3 h. It certainly appears to be complete soon after the first division at these dose levels. (3) During the recovery process, the cells continue to progress through the cycle, although more slowly than unirradiated cells. (4) The kinetic pattern of recovery for asynchronous cells exposed to fractionated doses is due to the combined effects of partial synchronization of survivors, rapid recovery from sub-lethal damage, and subsequent cell progression through the cycle.

EFFECTS OF INOSITOL-DEFICIENCY ON YEAST WITH PARTICULAR REFERENCE TO CHEMICAL COMPOSITION OF THE CELL AND OF THE CELL WALL

By Dr. S. W. CHALLINOR, Dr. D. M. POWER*
and Dr. R. J. TONGE†

Department of Biochemistry, The University, Edgbaston, Birmingham, 15

INTERESTING changes in the morphological and physiological characters of *Saccharomyces cerevisiae* were observed when this brewer's yeast was grown in media lacking inositol[1]. Thus, in such media growth is restricted, the yeast cells clump together to form aggregates, the fat content of the cell is greatly increased and the cell wall is considerably weakened[1,2]. This article describes other effects of inositol-deficiency and reports on its influence on the chemical composition of both the cell and cell wall.

The yeast was grown at 30° in a glucose, ammonium salts medium containing growth factors including inositol, 1 mg/100 ml. (complete medium), and in the same medium lacking inositol (deficient medium) in 300 ml. volumes in culture bottles (Glaxo pattern, 2·5 l. capacity)[2]. After incubation for 4–5 days the yeast was gathered on the centrifuge, washed and freeze-dried. The yields (dry weight) were 600 mg and 300 mg and the yeast is named 'normal' and 'deficient', respectively.

Preliminary observations of the ribonucleic acid content of the yeast growing in the complete and that in the deficient media were made at five different stages of growth. No appreciable differences were observed between the RNA contents of cells of the 'two yeasts' at comparable physiological ages. This finding is similar to that recorded by other workers[3] for the related yeast *Saccharomyces carlsbergensis*.

Manometric measurements were made on the cells and on particle-free cell-extracts of each of the two yeasts. Deficient cells respired glucose at a normal rate but possessed impaired fermentative power both aerobically and anaerobically. Deficient particle-free extracts evolved carbon dioxide much more slowly than normal extracts from glucose and from each of four glycolysis intermediates.

The remainder of this article deals mainly with analyses of the normal and deficient cells and of their walls. Cells were ruptured by shaking in the Mickle disintegrator and the walls isolated from cell debris by differential centrifugation. The walls were washed very thoroughly (fifty times) with water, freeze-dried, weighed and were found to constitute 10·5 and 10·3 per cent of the dry weight of the deficient and normal cells respectively. The similarity of these results is perhaps surprising in view of the marked differences observed in chemical composition and in other properties. Analytical results are expressed as percentage dry weight of the whole cells or walls respectively unless otherwise stated. Lipid analyses are given in Table 1.

Table 1. Lipids in the Normal and Deficient Cells and Cell Walls

	Cells		Walls	
	Deficient %	Normal %	Deficient %	Normal %
'Purified' lipid	48	19	6·7	6·7
Lipid-inositol*	0·32	0·92	0·2	0·4
Lipid-phosphorus*	0·37	0·89	0·5	1·1

* Expressed as percentage of the lipid present in the cell or in the wall

The lipids present in whole cells were extracted after rupturing in the Mickle cell disintegrator. Extraction of the broken-down cells or of the walls was carried out at room temperature under nitrogen with neutral chloroform–methanol mixtures (2 : 1 v/v) followed by extraction with acidic (1 per cent hydrochloric acid) chloroform–methanol mixtures. 'Purification' of the combined crude extracts was effected by the washing procedure of Folch, Lees and Sloane Stanley[4]. Increase in lipid content resulting from inositol-deficiency, previously reported[1,2] (for lipid material extracted with light petroleum), was again observed. Thus the 'purified' lipid content (48 per cent) of the deficient yeast was approximately two and a half times as great as that (19 per cent) of the normal yeast. In contrast, the 'purified' lipid contents of the cell walls of each of the two yeasts were the same—6·7 per cent of the dry weight of the wall.

---

* Present address: Atlantic Regional Laboratory, Halifax, Nova Scotia, Canada.

† Present address: Unilever Research Laboratory, Sharnbrook, Bedford.

Inositol present in these lipids was estimated by microbiological assay using *Schizosaccharomyces pombe*[5]. The deficient cell-lipids contained a lower percentage of inositol than the normal cell-lipids—0·32 versus 0·92 per cent—but when the *amounts* of total lipid-inositol present are considered (that is, after allowing for the higher lipid content of the deficient cells) the difference was small. In contrast, the deficient wall-lipids contained much lower amounts of inositol than the normal wall-lipids—0·2 versus 0·4 per cent—these latter percentages are proportional to the total amounts of inositol present in the wall-lipids, since each wall contains the same percentage (6·7 per cent) of lipid.

The total inositol contents of the cell and of the wall were also determined. Rather less inositol was found in the deficient cell—0·32 versus 0·44 per cent—whereas the deficient wall contained much less—0·02 versus 0·05 per cent—than the corresponding normal wall.

From the results of the two foregoing paragraphs it would appear: (1) that the yeast, when grown under conditions of inositol-deficiency, does have a lowered content of inositol in the cell and especially in its wall; (2) that the amount of inositol made available to cell-lipids is only slightly lowered, whereas that available to the wall-lipids is much reduced. The cell-lipids appear to have priority, as it were.

Phosphorus in the 'purified' lipids was estimated by the micro-method of Dryer, Tammes and Routh[6]. The percentage of phosphorus in the deficient cell-lipids was much reduced, 0·37 versus 0·89 per cent, but, after allowing for the much greater proportion of lipid present in the deficient yeast, the amounts of lipid phosphorus in the two yeasts were essentially the same. If the tentative assumption were made that the percentage of lipid-phosphorus gives some indication of the content of phospholipids the foregoing results would suggest that the two yeasts contained approximately the same amounts of this type of lipid; the increased amount of lipid observed in the deficient yeast could then be explained as due to an increase in the non-phosphorus-containing lipids.

In contrast to the foregoing results for cell-lipids the deficient wall-lipids contained much less phosphorus than the normal wall-lipids—0·5 versus 1·1 per cent. When these results are considered in conjunction with the lowered content of inositol, it seems possible that the deficient wall-lipids contain a reduced content of phosphoinositides. Such a finding may help to explain the fragility[1,2] of the wall of the deficient cell.

The fatty acids present in the wall-lipids were examined by gas-liquid chromatography and the relative proportions of the eleven fatty acids detected in each of the wall-lipids were essentially the same. A large proportion (76 per cent) of the fatty acids was unsaturated.

The cell walls were further examined and their contents of carbohydrate and protein were studied.

Total carbohydrate was estimated by the anthrone method. The polysaccharide glucan was estimated, after hydrolysis with acid, by glucose-oxidase; mannan was then determined by difference. Glucosamine was estimated after acid hydrolysis (hydrochloric acid) by the method of Cessi and Piliego[7].

Total carbohydrate constituted approximately 70 per cent of the normal wall and consisted mainly of the polysaccharides glucan (37·5 per cent) and mannan (31·6 per cent); a small amount of glucosamine (0·7 per cent) was also present. These findings are in general agreement with those of other workers for this species of yeast[8]. The foregoing three constituents were present in quite different proportions in the deficient wall—glucan was greatly increased (47·9 per cent), mannan greatly decreased (15·4 per cent) and six times as much glucosamine (4·2 per cent) was present.

Nitrogen was estimated by micro-Kjeldahl and protein calculated in the normal way after allowing for the nitrogen present as glucosamine. The normal wall contained much more protein than the deficient wall (15·9 versus 11·1 per cent).

The amino-acids present in the protein were detected by two-dimensional paper chromatography (butanol/acetic/water, 12 : 3 : 5 vol. and phenol, ammonia) after spraying with ninhydrin; estimation was carried out by means of an amino-acid auto-analyser (Technicon, Ltd.). Most of the naturally occurring amino-acids were present—seventeen in the normal wall and sixteen in the deficient wall; threonine was the most abundant and serine, glutamic and aspartic acids were also present in relatively large amounts in each of the walls. The dicarboxylic amino-acids formed a greater, and the basic amino-acids a much smaller, proportion of the total amino-acid content of the deficient wall. Only small amounts of the sulphur-containing amino-acids cystine and methionine were present in the normal wall; the deficient wall contained a smaller percentage of cystine and no detectable methionine.

The changes in composition of the cell-wall described above are of a major character. Compared with the normal the deficient wall contains materially different amounts of the two polysaccharides glucan and mannan, much more glucosamine, less protein (no methionine constituent), the same proportion of lipids which, however, have a lower phosphorus content and much less inositol both in the wall itself and in the wall-lipids. The decreased amounts of mannan and protein may indicate incomplete formation of the inner membrane (which, according to Northcote and Horne[9], is made up in part of these two substances) and this might account for the observed fragility of the inositol-deficient wall.

The results outlined in this article show that inositol-deficiency has a profound influence on the chemical composition of both the cell and its wall. These changes occur in yeast grown in the presence of oxygen in media containing no added inositol. Some of these changes have also been shown to occur in yeast grown in the presence of sub-optimal amounts of inositol.

Preliminary observations on yeast grown anaerobically in media containing oleic acid and ergosterol but lacking inositol have been carried out. The anaerobically grown deficient yeast cell contained essentially the same proportion (19 per cent) of lipid as the corresponding normal yeast, that is, increased formation of lipid in the cell did not occur. This very interesting result poses the question: Are the other effects of inositol-deficiency, as described here, also absent in anaerobically grown yeast? This question cannot be answered fully at present. Differences between the chemical composition of the walls of the anaerobically grown deficient and normal cells have in fact been observed, but these differences cannot yet be described more precisely, as preliminary results only are available.

We venture to suggest that investigations such as these on the weakened wall of the cell grown under conditions of inositol-deficiency may help in the understanding of the build-up of the wall of the normal healthy cell and, perhaps eventually, of the functions it performs.

DEOXYCORTICOSTERONE ACETATE AND EXPERIMENTAL ATHEROSCLEROSIS IN CHOLESTEROL-FED RABBITS

By Dr. G. B. ROSSI, P. ORIENTE, L. COSCIA PORRAZZI, A. VECCHIONE and R. CERQUA

Institute of Pathological Anatomy and Institute of Medical Pathology, School of Medicine, University of Naples

MOST recent work on the pathogenesis of atherosclerosis shows that probably the most important factors involved are: (*a*) changes in lipidic metabolism; (*b*) changes in the arterial wall, which could induce the deposition of plasmatic lipids into some particular vascular regions[1]. Among the endogenous factors regulating lipid metabolism, hormones seem very important, and for this reason their part in the genesis of atherosclerosis needs to be elucidated[2]. In this respect, cortisone, hydrocortisone, prednisone and corticotropin have been found capable of: (*a*) increasing the serum-levels of cholesterol and of low-density lipoproteins; (*b*) inhibiting atherogenesis in cholesterol-fed rabbits[2]. Similar results have also been obtained by other authors[3-7].

On the other hand, it has been previously shown[8-10] that hyaluronidase induces hypocholesterolæmia and more severe atheromasic lesions in cholesterol-fed rabbits, presumably because of an increased vascular permeability due to hyaluronidase. Adlersberg *et al.*[11], confirming the former and the latter results, have suggested that the effect of cortisone and its derivatives could be due to an antihyaluronidase action, already demonstrated by Benditt *et al.*[12] under different experimental conditions.

On the contrary, few investigations have been carried out on the relationships between deoxycorticosterone acetate (DCA) and both serum cholesterol-levels and atherosclerosis in cholesterol-fed animals.

However, it has already been shown that DCA, like hyaluronidase: (*a*) reduces the viscosity of the ground substance of connective tissue[13]; (*b*) depolymerizes the mucoproteic complexes of the ground substance[14,15]; (*c*) enhances the effect of hyaluronidase in stimulating osmosis[16,17]; (*d*) changes the vascular permeability when in high doses[18]. Furthermore, the results available on the relationships between DCA and atherosclerosis are often contradictory. In fact, according to refs. 19–22, DCA induces hypocholesterolæmia and decreases serum level of low-density lipoproteins and phospholipids in cholesterol-fed rabbits, dogs and chickens. This effect has been shown to be quite similar to that shown by hyaluronidase under the same experimental conditions[23]. On the other hand, a slight increase in cholesterolæmia has been demonstrated in dogs treated with low doses of DCA[24], while no changes of the serum levels of cholesterol have been found in rabbits treated with DCA[25]. The corresponding morphological findings concerning the arterial changes are also contradictory.

Preliminary investigations have been carried out by Cali and one of us (G. B. R.)[26] on the action of DCA on cholesterol-fed rabbits, with regard to the aorta only. Much more severe changes have been observed in aortæ of the cholesterol + DCA-fed rabbits than in those of the controls.

On the basis of the foregoing considerations and results, 87 female rabbits (average weight, 2·500 kg) were fed a high cholesterol diet (0·2 g/kg a day *per os*), in order to ascertain the possible effect of DCA on the cholesterolæmias and atherosclerosis of the hyperlipæmic rabbits. Three successive experiments were carried out, the first and the second with 25 animals each, fed with cholesterol for 60 days, and the third with 37 rabbits, fed with cholesterol for 67 days. In the first experiment, 13 out of the 25 rabbits were treated with 1 per cent DCA suspension in 10 per cent 'Tween 80' water solution at a dose of 12 mg/kg/day (300 mg, total), during the last 10 days of feeding with cholesterol, subcutaneously. In the second experiment, during the last 10 days of treatment, six animals received subcutaneously the foregoing dose of DCA (300 mg, total) and six were given the same DCA suspension at the dose of 18 mg/kg/day (450 mg, total) subcutaneously. The 37 animals of the third experiment were divided for the last 10 days of the treatment with cholesterol, in the following way: 9 animals were treated with cholesterol only (Chol), 11 rabbits received cholesterol + the foregoing suspension of DCA at a dose of 12 mg/kg/day (300 mg, total) (Chol + DCA + Tw), 8 animals were given cholesterol + 3 ml. of 10 per cent 'Tween 80' water solution a day (Chol + Tw), and finally, 9 animals were treated with the same dose of DCA, but given in a 2·5 'Vaseline' oil solution, besides cholesterol (Chol + DCA). DCA and 'Tween 80' were administered by subcutaneous way. Blood was drawn from the marginal vein of the ear of rabbits, after a fasting period of 12 h, before, during and after the administration of DCA and 'Tween 80'. Serum total cholesterol-levels were dosed according to the methods of Bloor and Knudson[27] in the first and second experiments, and of Pearson *et al.*[28] in the third experiment. Each value is the average of two determinations.

Four cross-sections of the hearts of the 37 animals of the third experiment, previously fixed in 10 per cent neutral formalin, were cut with a freezer microtome and the slices stained with sudan III and hæmatoxylin. At least 40 frozen slices were examined for each heart.

The relationships between the averages of the cholesterol values of the different groups of animals are shown in Figs. 1, 2 and 3. The statistical evaluation of data, carried out by means of calculation of Student's '*t*' and variance analysis, is illustrated in Table 1.

It has been pointed out that: (*a*) DCA induces a decrease of serum cholesterol-levels. This decrease is the more evident the higher were the serum cholesterol-levels

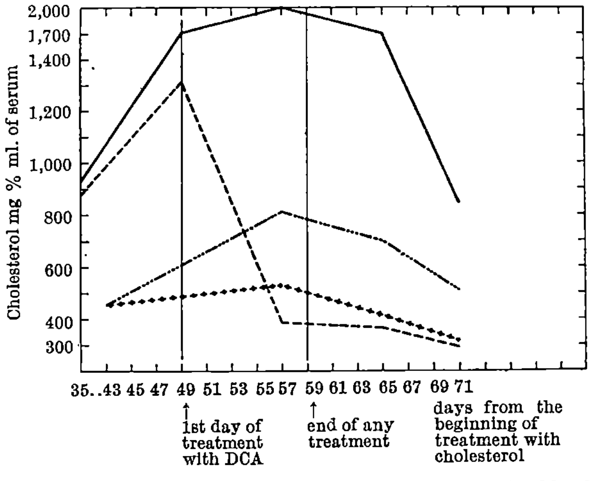

Fig. 1. First experiment. The averages of the serum cholesterol-levels of rabbits treated with DCA + cholesterol, and with cholesterol only, are reported. The experiment has been divided in two parts, because of the great difference between the values of some cholesterolæmias. Average of: ——, controls part No. 2; – – –, DCA treated animals part No. 2; + + + +, DCA treated animals part No. 1; —··—, controls part No. 1

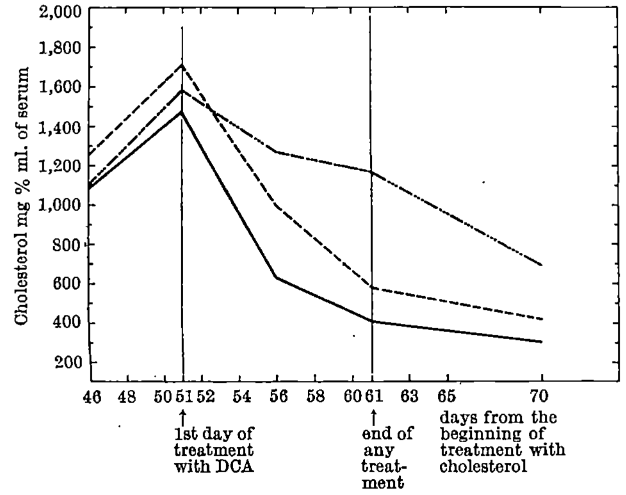

Fig. 2. Second experiment. The averages of the cholesterolæmias of the two experimental groups (rabbits treated with 300 mg and with 450 mg of DCA) and of control group are reported. ——, Average of values of rabbits treated with 300 mg DCA; – – –, average of values of rabbits treated with 450 mg DCA; —··—, average of controls

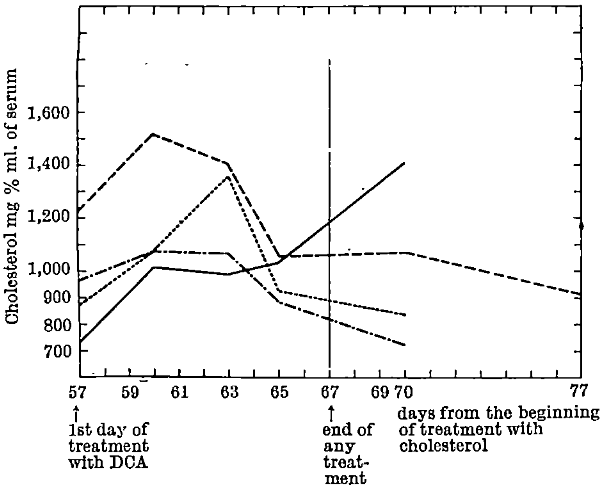

Fig. 3. Third experiment. The averages of the cholesterolæmias of the two experimental groups (Chol+DCA+Tw, – – – –; Chol+DCA, - - - -) and of the two control groups (Chol, ——; Chol+Tw, —·—·) are reported

Table 1. Statistical Evaluation of the Differences between the Averages of Cholesterolæmias of the Rabbits' of Experimental and Control Groups

(The standard deviation has been calculated for each average value)

1st Exp. (Student's '*t*' factor has been calculated):

(*a*) At the 43rd day $P > 0{\cdot}05$ for 18 *d.f.*
(*b*) At the 49th day $P > 0{\cdot}05$ for 3 *d.f.*
(*c*) At the 57th day $P < 0{\cdot}02$ for 23 *d.f.*
(*d*) At the 65th day $P < 0{\cdot}02$ for 23 *d.f.*
(*e*) At the 71st day $P < 0{\cdot}01$ for 21 *d.f.*

2nd Exp. (1) Variance analysis between the averages of the three groups (the factor '*F*' has been calculated):

(*a*) At the 51st day $P > 0{\cdot}05$ for 24 *d.f.*
(*b*) At the 56th day $P < 0{\cdot}02$ for 24 *d.f.*
(*c*) At the 63rd day $P < 0{\cdot}01$ for 24 *d.f.*
(*d*) At the 70th day $P < 0{\cdot}01$ for 23 *d.f.*

(2) Student's *t* factor has been calculated between the averages of cholesterolæmias of rabbits treated with 300 mg of DCA and of those treated with 450 mg of DCA:

(*a*) At the 51st day $P > 0{\cdot}05$ for 11 *d.f.*
(*b*) At the 56th day $P < 0{\cdot}05$ for 11 *d.f.*
(*c*) At the 63rd day $P > 0{\cdot}05$ for 11 *d.f.*
(*d*) At the 70th day $P > 0{\cdot}05$ for 10 *d.f.*

3rd Exp. (1) Variance analysis between the averages of the four groups (the factor '*F*' has been calculated):

(*a*) At the 65th day $P > 0{\cdot}05$ for 30 *d.f.*
(*b*) At the 70th day $P > 0{\cdot}05$ for 26 *d.f.*

(2) Student's '*t*' factor has been calculated between the averages of Chol+DCA+Tw group and of Chol+DCA group:

(*a*) At the 70th day $P > 0{\cdot}05$ for 13 *d.f.*

at the moment of DCA injection. The differences between the averages of cholesterolæmias of experimental and control rabbits are highly significant in the first and second experiment. An examination of Fig. 3 seems to indicate a decreasing effect of DCA in both the experimental groups (Chol + DCA + Tw and Chol + DCA), but the difference between the values of the experimental and control groups is not statistically significant. This could be due, in our opinion, to the small number of rabbits treated for each group and to an occasionally high biological variability. (*b*) The induced decrease of cholesterolæmia is not proportional to the injected dose of DCA. In fact, the difference between the averages of cholesterolæmias of the rabbits treated with 300 mg and, respectively, with 450 mg of DCA, is not significant. (*c*) 'Tween 80' does not interfere with the foregoing effect of DCA. In fact, no significant difference has been shown between the cholesterolæmia decrease induced by the DCA suspension in 'Tween 80' solution and that induced by DCA 'Vaseline' oil solution. Moreover, much higher doses of 'Tween 80' have been found capable of increasing and not decreasing, serum cholesterol-levels of cholesterol-fed rabbits[29,30].

So far as the morphological pictures are concerned, it has been observed that: (*a*) The coronary arteries of the animals of the Chol + DCA + Tw group show much more severe atheromatous changes (lipidic infiltration into the entire vascular wall) (Fig. 4) than those of the rabbits of the Chol group. Furthermore, the atheromasic lesions seem to be, as for the former group, very frequent in the majority of the small coronary vessels and also spread over great portions of the wall of each vessel (Fig. 5). (*b*) The coronary changes found in the animals of the Chol + Tw group are not so evident as those found in the rabbits of the Chol group (Fig. 6); this could be due to the small dose of cholesterol given in this experiment. (*c*) Finally, the vascular lesions of the animals of the Chol + DCA group are quite similar to those of the Chol + DCA + Tw group, both for their severity and for their frequency and diffusion. These results seem to indicate that: (*a*) DCA induces more severe and diffuse atheromatous lesions in DCA + cholesterol-treated animals than those observed in the controls. (*b*) 'Tween 80' does not interfere with the fore-

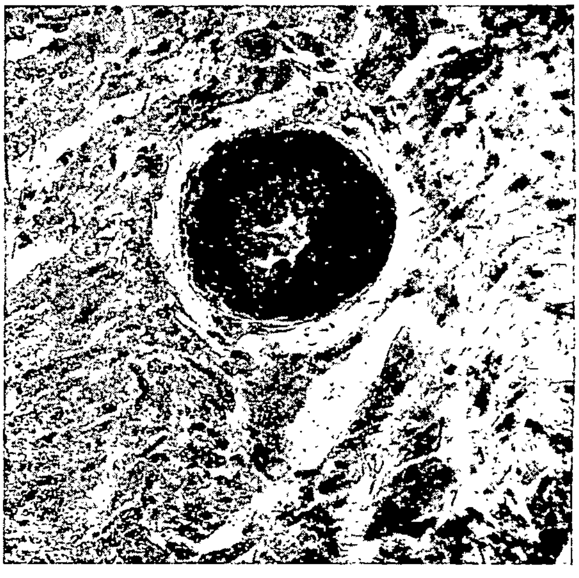

Fig. 4. Cross-section of a small coronary vessel, showing a massive deposition of sudanophilic material into the entire vascular wall (second group) (sudan III and hæmatoxylin, × 900)

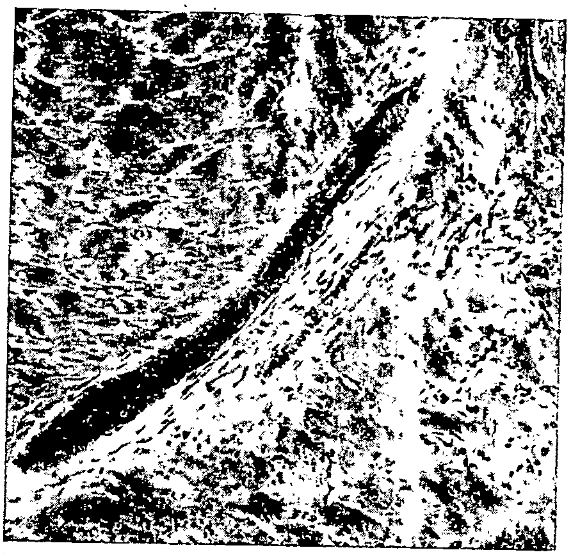

Fig. 5. A tangential section of a coronary vessel, in which the lipidic infiltration is spread over a great portion of the vascular wall (second group) (sudan III and hæmatoxylin, × 360)

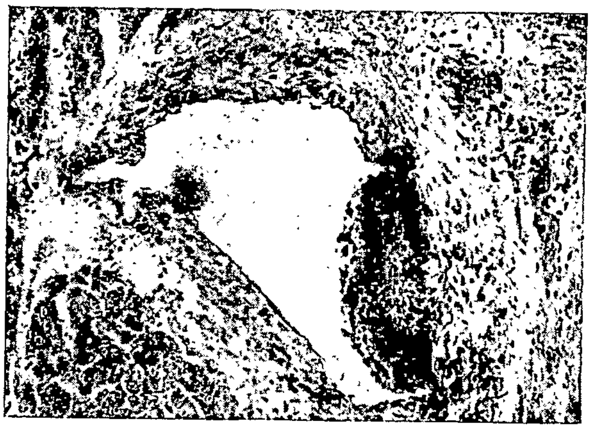

Fig. 6. A cross-section of a coronary vessel, with a small plaque limited in size and in extension (control group) (sudan III and hæmatoxylin, × c. 270)

going effect of DCA, which agrees with the observations that have been made of the serum cholesterol-levels. Moreover, much higher doses of 'Tween 80' have been found capable of slightly inhibiting, and not enhancing, the experimental atherosclerosis[29,30]. Similar results have been obtained on aortic specimens of animals treated in the same way as in this experiment[26].

From the foregoing considerations, DCA seems to play an important part in the pathogenesis of the plasmatic and tissue changes of experimental atherosclerosis due to hypercholesterolic diet.

On the basis of the suggested resemblance between the mechanism of DCA and hyaluronidase action, it has been suggested[26] that DCA probably interferes with the hyaluronic acid–hyaluronidase system of the chromotrope ground substance of the sub-intimal connective tissue. The depolymerization of the mucopolysaccharides of the ground substance could favour and increase the deposition of plasmatic lipids into the vascular wall, inducing both a decrease of the serum cholesterol-level and more severe atheromasic changes of the arterial wall.

An interference of DCA with the metabolism of thyroid gland is also possible. In fact, it has been demonstrated that thyroid hormones are capable of lowering serum cholesterol-levels and inhibiting atherosclerosis in cholesterol-fed rabbits[31] and chickens[32], whereas hypophysectomy[33], and hypothyroidism due to anti-thyroid drugs[34–38], enhance more and more hypercholesterolæmias and atheromatous lesions in cholesterol-fed rabbits[33], and succeed in inducing very high cholesterolæmias and atheromatous changes even in less-susceptible animals (dogs[34], rats[35–37] and hamsters[38]), fed with hypercholesterolic diet. Furthermore, it has been shown that the administration of cholesterol induces thyroid hypoplasia in rabbits and guinea pigs (species susceptible to develop high cholesterolæmias and experimental atherosclerosis) and thyroid hyperplasia in rats and hamsters (species less susceptible to show hypercholesterolæmias and experimental atherosclerosis)[39,40].

In this respect, DCA could inhibit the thyroid gland by means of the known 'adrenal cortex → hypophysis → thyroid gland' mechanism. If this were the case, it would be expected that DCA could, even slightly, increase thyroid hypoplasia due to the cholesterol feeding, inducing higher cholesterolæmias and, in this way, more severe arterial changes than in the controls. But the experimental results concerning the serum cholesterol-levels are quite opposite, and this seems to strengthen the aforementioned hypothesis of a direct action of DCA on the genesis of the deposition of plasmatic lipids into the arterial wall.

For all these considerations, even though a possible slight thyroid inhibition by DCA cannot be excluded, we suggest that the aforementioned interference of DCA in the hyaluronic acid–hyaluronidase system could be at least one of the most important mechanisms of DCA action on the atherogenesis of cholesterol-fed rabbits.

URINARY TRYPSIN INHIBITOR (MINGIN): TRANSFORMATION INTO A NEW TRYPSIN INHIBITOR BY ACID HYDROLYSIS OR BY SIALIDASE

By DR. TAGE ASTRUP and UWE NISSEN

Institute for Medical Research of the James F. Mitchell Foundation, Washington, D.C.,
and Technical University of Denmark, Copenhagen

THE trypsin inhibitor in human urine, purified by Shulman[1] and by Astrup *et al.*[2], is an interesting compound. In various physiological and pathological states it is excreted in increased amounts, apparently influenced by the pituitary-adrenal system[3]. Thus the diurnal excretion is augmented after administration of ACTH or cortisone, during fever, in the latter part of pregnancy, and in general after stress reactions. The compound is also an inhibitor of testicular hyaluronidase[4]. A parallelism between increase in level of serum trypsin inhibitor and the increase in diurnal excretion of the urine inhibitor has been reported[5]. Presence of ε-aminocaproic acid greatly potentiates its inhibition of urokinase-induced fibrinolysis[6].

Astrup *et al.*[2] prepared the inhibitor from human pregnancy urine and also suggested the term 'mingin' (from Latin: mingo) for this particular compound. Later, the compound was purified until it was homogeneous over a wide range of *p*H by paper electrophoresis, and it appeared that no further increase in trypsin-binding capacity could be obtained. A final capacity of 1·2 mg/mg crystalline trypsin ('Trypure', Novo Laboratories, Copenhagen: 24·4 Anson units/mg) was regularly reached. Assuming a molecular weight of about 25,000 for trypsin, this would, on a mole-to-mole basis, give a molecular weight for the inhibitor of about 30,000. Mingin is an extremely acid compound. Its isoelectric point is at *p*H 2·1. After complete acid hydrolysis, paper chromatography showed the presence of common amino-acids (including lysine and arginine) and of hexosamine. There was 4–5 per cent carbohydrate expressed as glucose[7].

We have now found that mingin can be transformed into a new trypsin inhibitor without loss of activity. This article describes experiments demonstrating the formation and some properties of the new inhibitor which differs from mingin in many respects. All experiments were performed with preparations of mingin having a trypsin-binding capacity of 1·2–1·3 mg/mg trypsin.

First an explanation was sought for the extraordinary low isoelectric point which could not be accounted for by the amino-acid composition. Analyses for sulphate and phosphorus were negative so that sulphuric acid or phosphoric acid groups could not be present. Our attention was then directed to the possible presence of sialic acid since our previous data had suggested a similarity with acid glyco-proteins[7].

When the 'direct Ehrlich' reaction[8] was applied to a solution of mingin (10 mg/ml.) no immediate colour reaction was obtained, demonstrating the absence of free reactive compounds. After heating the reaction mixture in boiling water for 30 min, 6 mg mingin produced a colour corresponding to 0·24 mg neuraminic acid, equal to 4 per cent (Beckman *DB* spectrophotometer. Linear dilution curves. Assayed against a sample of N-acetyl neuraminic acid, Nutritional Biochemicals Corp., Sialic acid concentrate; Lot No. 5487; Declaration of assay: 20 per cent).

The thiobarbituric acid method[8,9], applied to a solution containing 0·5 mg mingin/ml., yielded, after hydrolysis for 1 h at *p*H 2 and 80°, 2·3 per cent neuraminic acid (same reference sample as above).

Though the results of the two methods do not agree, they demonstrate that sialic acid reactive material is present in mingin in significant amounts. So far the reason for the discrepancy is unknown. However, differences between assays performed by the 'direct Ehrlich' reaction and by the thiobarbituric acid method have been reported by various authors and several explanations have been offered[10]. It could be of significance that the proportion between the two assays performed on mingin is approximately 58 per cent since this is the difference reported when the two methods are applied to *N*-glycolloyl neuraminic acid[10]. Using a pure compound, this could suggest the presence of this acid in mingin.

The release of large quantities of sialic acid during mild acid hydrolysis was a surprise, since mingin appears to be extremely stable in acid aqueous solutions. Thus little trypsin-binding capacity is lost by heating for 30 min at 100° C between *p*H 2 and 5. Above *p*H 5 there is rapid destruction[11]. It therefore appears that sialic acid can be removed without loss of trypsin-binding capacity, so that combination with sialic acid is not required for the inhibitor activity of mingin. After release of sialic acid, the remaining molecule would be more neutral than the original mingin, and it should be possible to trace the formation of the new compound by paper electrophoresis.

Hence, solutions of mingin were hydrolysed as in the thiobarbituric acid assay. Paper electrophoresis was performed in 0·1 M glycine-hydrochloric acid buffer at *p*H 2·3 where mingin would show little migration. Two components were observed. One of these migrated as untreated mingin. The other showed a much higher mobility at the *p*H value of the test, and therefore represented a compound considerably less acid than the original mingin. This assumption was supported by the observation that the new compound stained with bromphenol blue like a normal protein, while mingin is only weakly stained. This fact prevented a quantitative evaluation of the amounts separated on the electrophoresis strip. After elution, trypsin-binding capacity was found in both components. Hence, the formation of a new trypsin inhibitor, less acid than the original mingin, and derived from this by release of sialic acid, had been demonstrated.

The conditions for formation of the new inhibitor were then investigated, by varying the *p*H, temperature, and period of heating. Inhibitor activity was assayed on casein by ultra-violet spectrophotometry[12], using a Beckmann *DB* spectrophotometer with hydrogen lamp. Paper electrophoresis of the treated solutions was performed at *p*H 2·3 and 4·5. At the first *p*H mingin showed little migration, and at the latter the new compound migrated slowly. Conditions were established, at which little of the original mingin would remain as indicated on the electrophoresis strip, while most of the inhibitor activity was retained. Numerous experiments led to the final choice of 50 mg mingin/ml. in 0·1 M glycine-hydrochloric acid buffer at *p*H 2·3 and 4 h at 100°. About 75 per cent of the inhibitor activity was retained while less than 20 per cent of the original mingin remained. In general, the loss in activity was lower in these experiments than in the thermostability investigations previously reported. Most probably this is due to a stabilizing effect of the high concentration used in the preparative heat treatment, approximately 2,000 times higher than before. At a still lower *p*H the activity was rapidly destroyed. Thus at *p*H 0·8 after 1·5 h at 100° only 11 per cent inhibitor activity remained.

The next step was to see whether sialic acid could be removed by enzyme action with retainment of inhibitor activity. Such a possibility seemed likely in view of the recent finding that sialic acid can be released from human serum cholinesterase with sialidase with no loss of activity[13]. Supposedly an enzyme inhibitor would be even more resistant than an active enzyme.

Hence, a solution (50 mg/ml.) of mingin in 0·1 M sodium acetate buffer, *p*H 5·2, was prepared and incubated at 37° with 1 mg/ml. of a sialidase preparation (Sigma Chemical Co., St. Louis, neuraminidase, purified from '*Cl. perfringens*', Lot No. 338–691). The inhibitor activity of the mixture remained constant over a prolonged period. After 2 weeks less than 10 per cent had been lost. After 5 days no trace of the original mingin could be seen by paper electrophoresis performed as described here, and a new spot had formed, resembling, in migration and stainability, that obtained after acid hydrolysis. After elution this new component was found to possess inhibitor activity.

The electrophoretic mobilities of mingin have been determined before[7] using a method of paper electrophoresis by which corrections for evaporation, electro-osmosis, adsorption, etc., could be introduced, and the values for free mobilities could be calculated[11]. In order to compare the acid-hydrolysed mingin with the sialidase-treated product, and also with the genuine mingin, solutions of these compounds were prepared as described above and studied by this method. The following buffers were used, all at ionic strength 0·1; glycine–hydrochloric acid, sodium acetate–acetic acid, *tris*, glycine–sodium hydroxide, carbonate–bicarbonate. The data obtained, calculated as described, are presented in Fig. 1. Each value is the average of 3–12 estimations.

The electrophoretic mobilities of mingin correspond to those previously published[7], but have been extended over a wider range of *p*H. The mobilities recorded for acid hydrolysed mingin and for sialidase-treated mingin produced identical curves. Hence, these two compounds were electrophoretically identical. The new curve was approximately parallel to the original mingin curve with a difference over the whole *p*H range of about $+5 \times 10^{-5}$ mobility units. A highly acid component of the molecule had been lost such as had been anticipated. As a result, the isoelectric point had moved from *p*H 2·1 to about *p*H 4·5, the difference being approximately 2·4 *p*H units. In both curves little change in electrical charge occurred between *p*H 5 and 8. In this respect the new compound behaves differently from human serum albumin though the isoelectric points are nearly identical. It is interesting to compare these results with those reported for the sialidase-treated cholinesterase[15]. There the difference in mobility was 2–3 $\times 10^{-5}$ units, while the isoelectric point changed from *p*H 3 to about *p*H 7, a difference of about 4 *p*H units. Apparently the difference in number of ionogenic groups per molecule was less than when sialic acid was released from mingin, while the influence on the zero net charge was higher. Both cholinesterase compounds were less acid than the corresponding mingin compounds.

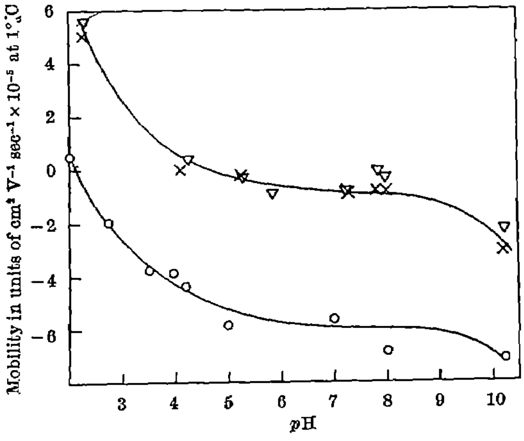

Fig. 1. Electrophoretic mobility of mingin (○), acid-hydrolysed mingin (▽), and sialidase-treated mingin (×)

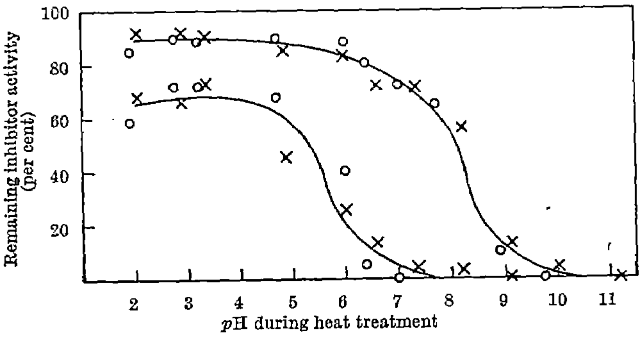

Fig. 2. Heat stability at 70° and 100° of mingin before (○) and after (×) treatment with sialidase

Since the thermostability curve is characteristic for mingin the thermostability of the new compound was investigated. Solutions of mingin and of a sialidase-treated compound, prepared as described, were heated for 1 h at 70° and 100° and at various *p*H values (using 0·05 M buffers as in the preliminary studies). The results are given in Fig. 2.

No difference is observed between the heat stability of the native mingin and of the sialidase-produced new compound. Apparently the heat stability, as the inhibitor activity, is a property of the protein moiety of the original mingin molecule. Loss of sialic acid does not change the heat stability of the protein part.

Separation and isolation of the new inhibitor were confirmed by column chromatography on a sulphonic acid resin (Fischer, 'Rexyn 101 (Na)'). After pretreatment of the column with 0·05 M acetic acid the acid- or sialidase-treated mingin solution, brought to *p*H 4, was passed through the column followed by 0·05 M acetate buffer, *p*H 4·25; by 0·1 M phosphate buffer, *p*H 7·6; and finally by 0·2 M sodium carbonate (*p*H ~ 10·6). The eluates were collected and brought to neutral reaction with N hydrochloric acid or solid sodium bicarbonate. Inhibitor activity was tested against trypsin by the plate method using unheated fibrin[16]. This method is less accurate for the assay of mingin for reasons explained before[11], but it requires little material and is easily performed on a large scale. Since no quantitative data were required for a separation of the active eluates from the inactive, this method was convenient. In the acid-treated solution two components were found. The first of these was eluted when the column was brought from *p*H 4·25 to neutral reaction. Native mingin behaved in the same manner on the column and this fraction therefore consisted of the unconverted mingin. The second component appeared when the *p*H was raised with carbonate. Sialidase-treated mingin produced only one component appearing in the second place.

It might be added that, in addition to sialic acid, other components of low molecular weight are released by acid hydrolysis or by sialidase treatment. They could be separated from the active compound by dialysis and gave a positive ninhydrin reaction, but so far have not been investigated.

This article is, to our knowledge, the first to describe a selective conversion without loss of activity of a natural protease inhibitor into a new inhibitor. We are at present engaged in a further characterization of the new inhibitor for which we would like to suggest the name 'minginin'. Its interaction with various proteases and fibrinolytic agents is being investigated. Several physiological questions are presenting themselves: What relation is there between inhibitors in blood and the inhibitor excreted in urine ? Does minginin exist as such in the organism ? Is the sialic acid-containing compound (mingin) derived from the sialic acid-free compound (minginin) or is the opposite true ? Does a coupling with sialic acid represent a new physiological mechanism of detoxication ? Or is it required for rapid excretion in the kidneys? It might be added for comparison that sialidase and a cholinesterase compound of low mobility have been observed in spinal fluid[13].

UPTAKE AND BINDING OF CHLORAMPHENICOL BY SENSITIVE AND RESISTANT ORGANISMS

By Dr. D. VAZQUEZ

Sub-Department of Chemical Microbiology, Department of Biochemistry, University of Cambridge

D-THREO-CHLORAMPHENICOL (CAP) inhibits bacterial growth by blocking protein synthesis at some stage in the transfer of amino-acids from transfer RNA to protein[1]. However, CAP does not inhibit growth of yeasts, protozoa (with the unique reported exception of *Tetrahymena pyriformis*[2]), plants and animals.

It has been previously reported that D-threo-chloramphenicol (methylene-^{14}C) (^{14}C-CAP) is taken up by *Staphylococcus aureus* and *Bacillus megaterium*. After breakage and centrifugal fractionation of the bacteria all the radioactivity is associated with the ribosomal and soluble fractions. ^{14}C-CAP is also bound by ribosomes from these bacterial species in cell-free systems; the binding is immediate, not dependent on energy, unaffected by the incubation temperature and very easily reversible[3]. ^{14}C-CAP binds to 70 *S* ribosomes and to the 50 *S* sub-unit obtained from them. In both cases K^{+} ions are required for the binding of ^{14}C-CAP (ref. 4).

In more recent investigations the binding of ^{14}C-CAP to bacterial ribosomes has been shown to be prevented by pre-incubating the ribosomes in the presence of CAP, streptogramin *A* (synonyms *PA* 114 *A*–1, ostreogrycin *A*, staphylomycin M_1), ostreogrycin *G*, erythromycin, spiramycin, angolamycin, lankamycin, methymycin, carbomycin and oleandomycin, but was unaffected by streptogramin *B* (synonyms *PA* 114 *B*–1, ostreogrycin *B*), staphylomycin *S*, echinomycin, aureomycin, terramycin, puromycin, streptomycin and viridogrisein (synonym etamycin). A close relationship between the binding site and the primary point of action of an antibiotic seems probable. Thus antibiotics which reduce ^{14}C-CAP binding may inhibit the same reaction whereas others, although inhibitors of protein synthesis, may act at a different locus. The binding of CAP to ribosomes appears to be very specific and is unaffected by pre-incubation of the ribosomes with the CAP isomers L-erythro-, L-threo-, and D-erythro-chloramphenicol.

The uptake of ^{14}C-CAP by sensitive and resistant organisms and the binding of the antibiotic to their ribosomes have been investigated in an attempt to elucidate: (*a*) the relationship between the uptake and binding of ^{14}C-CAP and the antibiotic sensitivity of the organisms; (*b*) the possible mechanisms of resistance to CAP.

The uptake of ^{14}C-CAP by different organisms has been investigated and the results are shown in Table 1. There is a close relationship between the uptake of ^{14}C-CAP by the organisms and their antibiotic sensitivity. The uptake of ^{14}C-CAP by *E. coli B* 150 was lower than the uptake by *E. coli B* and this could possibly explain the increased resistance of *E. coli B* 150 to CAP. Spheroplasts of *E. coli B* and *E. coli B* 150 were prepared by the technique described by Kohn[5] and uptake of ^{14}C-CAP into the spheroplasts was investigated. The uptake of ^{14}C-CAP was almost negligible for spheroplasts from the resistant mutant (Table 2). It is possible that the low uptake of ^{14}C-CAP by intact bacteria of the resistant

Table 1. UPTAKE OF ^{14}C-CAP BY DIFFERENT ORGANISMS

Organisms	Growth inhibited (μg CAP/ml.)	Incubation conditions: Medium	Incubation time	Incubation temperature	mμg ^{14}C-CAP taken up/mg organisms
Staphylococcus aureus Duncan	10	*A* (ref. 6)	20 min	37°	9·8
Bacillus megaterium KM	10	*CG* (ref. 7)	20 min	30°	7·5
Escherichia coli B	5	*CG*	20 min	37°	19·6
**Escherichia coli B* 150	> 300	*CG*	20 min	37°	5·6
Pseudomonas striata	10	*A*	20 min	25°	26·0
Saccharomyces fragilis Jörgenson	> 300	Yeast extract (ref. 8)	20 min	30°	< 0·5
Crithidia (*Strigomonas*) *oncopelti*	> 300	Peptone glucose (ref. 9)	8 h	25°	0·5
Tetrahymena pyriformis W	150	Proteose peptone (ref. 2)	8 h	25°	2·5

**E. coli B* 150 derived from *E. coli B*

The organisms were collected during the exponential phase of growth, resuspended at a concentration of 3 mg dry wt./ml. (*C. oncopelti* and *T. pyriformis* 0·1 mg dry wt./ml.) and incubated in suitable growth media at their optimal growth temperature in the presence of 2 μg ^{14}C-CAP/ml. At the end of the incubation, the organisms were cooled to 4°, centrifuged, rinsed twice with growth media, resuspended in water and the radioactivity determined. Corrections were made for ^{14}C-CAP present in the intercellular fluid.

Table 2. UPTAKE OF ^{14}C-CAP BY *E. coli B* AND *E. coli B* 150

	mμg ^{14}C-CAP taken up/mg bacteria Whole bacteria	Spheroplasts
E. coli B	15·6	12·1
E. coli B 150	4·9	0·6

Bacteria were incubated in *CG* medium supplemented with 25 per cent sucrose. Spheroplasts obtained by the method of Kohn (ref. 5) were also incubated in *CG* medium supplemented with 25 per cent sucrose. Uptake of ^{14}C-CAP was determined as described in Table 1.

strain (Table 2) was due to a penetration of the antibiotic into cellular components outside the plasma membrane and that the resistance of *E. coli B* 150 is due to the impermeability of the membrane to CAP.

Although a permeability barrier could explain the CAP resistance of some organisms, it does not explain the failure of CAP to inhibit protein synthesis in ribosomal systems from yeasts, mammalian tissues, pea seedlings and *T. pyriformis*. The binding of ^{14}C-CAP to ribosomes from CAP sensitive and resistant organisms has been investigated and the results are shown in Table 3. The degree of binding of ^{14}C-CAP to ribosomes from different bacterial species was very similar and only *S. aureus* ribosomes bound ^{14}C-CAP to a significantly smaller extent. This was possibly due to the fact that the duration of breakage of *S. aureus* in the ultrasonic disintegrator was larger than for the other bacteria[10]. If the time of breakage of *B. megaterium* was prolonged to 13 min the amount of ^{14}C-CAP bound by the ribosomes was reduced by 50 per cent. On the other hand, the amounts of ^{14}C-CAP bound by ribosomes from *E. coli B* and *E. coli B* 150 were very similar, suggesting that the resistance of *E. coli B* 150 is due to a decreased permeability of the bacteria to CAP; this result is in agreement with the finding reported by Okamoto and Minuzo[13] that protein synthesis by cell-free systems from a strain of *E. coli* resistant to CAP was sensitive to the antibiotic.

^{14}C-CAP was not bound to ribosomes from *S. fragilis*, *C. oncopelti*, *T. pyriformis*, rat liver and pea seedlings either in 10^{-2} M *tris*-hydrochloric acid buffer containing 10^{-2} M Mg^{++} and 0·2 M K^{+} or in the buffer systems used to study protein synthesis in cell-free systems of these organisms[2,11,12,14].

The results obtained in this work suggest that all bacterial ribosomes (sedimentation constant 70 *S*) are able to bind ^{14}C-CAP. The resistance to the antibiotic shown by *E. coli B* 150 is due to the impermeability of the bacterial membrane; ribosomes from this strain bind ^{14}C-CAP to the same extent as those from the parent sensitive strain.

Ribosomes (sedimentation constant 80 *S*) from other organisms were unable to bind ^{14}C-CAP and this finding could explain the resistance of yeasts, protozoa, mammalian and plant systems to CAP. *T. pyriformis*, although a protozoan, is sensitive to high concentrations of CAP, but it has been reported that synthesis of protein by a ribosome system from *T. pyriformis W* is not affected by the antibiotic[2].

Table 3. BINDING OF ^{14}C-CAP BY RIBOSOMES

Organisms and tissues	Method of breakage	Ribosomal preparation	mμg CAP bound/mg ribosomes
S. aureus, Duncan	Ultrasonic, 13 min	70 *S*	18
B. megaterium KM	(1) Osmotic shock	70 *S*	30
	(2) Ultrasonic, 2 min	70 *S*	29
E. coli B	Ultrasonic, 1 min	70 *S*	29
E. coli B 150	Ultrasonic, 1 min	70 *S*	30
P. striata	Ultrasonic, 45 sec	70 *S*	33
S. fragilis Jörgenson	(1) Hughes press	80 *S*	Less than 1
	(2) Osmotic shock	80 *S*	
	(3) Ultrasonic, 2 min	80 *S*	
C. oncopelti	High-speed blending with glass beads	80 *S*	
T. pyriformis W	High-speed blending with glass beads	80 *S*	
Rat liver	See reference 11	80 *S* Polysomes	
Pea seedlings	See reference 12	80 *S*	

^{14}C-CAP (1 μg/ml.) was added to a preparation of ribosomes in 10^{-2} M *tris*-hydrochloric acid buffer *p*H 7·4 containing 10^{-2} M Mg^{++} and 0·2 M K^{+}. After 2 min at 4° the suspension was centrifuged at 150,000*g* for 60 min and the radioactivity in the pellet determined. In control experiments non-radioactive chloramphenicol (100 μg/ml.) was present during the incubation period and ^{14}C-CAP was added at the end. Volume of incubation mixture was 2 ml. containing 4 mg of ribosomes.

The lack of CAP inhibition of protein synthesis by ribosomal systems from yeasts, protozoa, mammals and plants may therefore be due to the inability of their ribosomes to bind the antibiotic.

The variation in CAP binding by ribosomes is in agreement with the ability of the antibiotic to inhibit protein synthesis in cell-free systems. If CAP inhibits only as a result of binding to the ribosomes, there is no need to postulate the existence of an additional CAP sensitive step in bacterial protein synthesis which is absent from mammalian systems as has been proposed by von Ehrenstein and Lipmann[15].

CHLORAMPHENICOL AS AN INHIBITOR OF ENERGY-LINKED PROCESSES IN MAIZE MITOCHONDRIA

By C. D. STONER, DR. T. K. HODGES and PROF. J. B. HANSON

Department of Agronomy, University of Illinois, Urbana

IN the course of investigating the accumulation of calcium by maize mitochondria, it was observed that chloramphenicol in the concentrations used to inhibit ion accumulation by plants acted as an uncoupling agent[1]. Superficially, the compound seemed to act in the same fashion as the classic uncoupling agent, DNP (2,4-dinitrophenol). It appeared that the uncoupling properties of chloramphenicol could be responsible for the inhibition of ion accumulation.

We have now made additional observations on the action of chloramphenicol as part of present-day investigations of mitochondrial swelling and contraction, calcium uptake and ATPase. These observations indicate that chloramphenicol has a site of action distinct from DNP or oligomycin, and that it may act on one of the high-energy intermediates postulated for ATP formation and other energy-linked processes[2-10].

The experiments were conducted with mitochondria isolated from the shoots of ætiolated maize seedlings[1]. The properties of maize mitochondria with respect to reversible swelling, ion accumulation, and ATPase activity are not very different from those described for animal mitochondria. Complete descriptions will be published separately. We here abstract from the major work sufficient detail to compare the action of chloramphenicol with that of DNP and oligomycin.

Maize mitochondria swell spontaneously when placed in 0·2 M potassium chloride + 0·02 M *tris* (*p*H 7·5), and will contract on addition of ATP or succinate (Fig. 1). The curves are like those recently reported by Lyons and Pratt[11] for cauliflower mitochondria, except that these authors did not report substrate-induced contraction. In the experiments reported here the swelling and contraction were followed by changes in optical density at 520 mμ, but we have verified that volume changes are involved by measuring wet weight, and by electron microscopy. Pyruvate-malate or NADH will serve as well as succinate in powering contraction. Cyanide inhibits succinate-powered contraction, but not ATP-powered. Phosphate and magnesium are not required for succinate-induced contraction; on the contrary, phosphate is inhibitory (Table 1). Oxidizable substrate produces a more rapid contraction than ATP (Fig. 1).

Table 1. INHIBITION OF CONTRACTION BY UNCOUPLING AGENTS AND PHOSPHATE

Additive	% inhibition of contraction	
	Succinate	ATP
Dinitrophenol 5×10^{-4} M	56·9	64·0
Oligomycin 2 μg/ml.	−4·4*	79·5
Chloramphenicol 5×10^{-3} M	2·5	56·5
Phosphate 10^{-3} M	45·6	—
Magnesium 10^{-3} M	−5·4*	—
Phosphate and magnesium	46·7	—

Experiments with DNP, oligomycin, and chloramphenicol were performed as in Fig. 1, with the inhibitor added initially. Phosphate and Mg were added with the succinate. Inhibition was calculated from Δ optical density just before and 2 min after adding succinate or ATP.

* Promotion; these values and that with chloramphenicol (succinate-powered) are within errors of measurement.

Dinitrophenol accelerates the swelling-rate, but there is no change in final swollen volume (Fig. 1). Both succinate- and ATP-powered contraction are inhibited by DNP. Similar experiments have been done with the more effective uncoupler, *m*-Cl-CCP (carbonyl cyanide *m*-chlorophenylhydrazone). Except for the fact that lower concentrations are needed (about 10^{-5} M), the results are the same as with DNP. Neither DNP nor *m*-Cl-CCP is efficient in inhibiting contraction unless concentrations are used which virtually eliminate oxidative phosphorylation.

Table 1 compares the inhibitions of contraction found with DNP with those given by oligomycin, chloramphenicol and phosphate. Neither oligomycin nor chloramphenicol affects succinate-powered contraction, but they are effective with the ATP-powered system. Low concentrations of phosphate inhibit succinate-powered contraction.

Oligomycin blocks ATP-powered uptake of calcium but has little effect on substrate-powered uptake (Table 2; see also Brierley *et al.*[6] and Lehninger *et al.*[8]). Chloramphenicol, however, inhibits both the substrate-powered uptake[1] and the ATP-powered uptake (Table 3). Hence, although one cannot distinguish between oligomycin and chloramphenicol in the contraction system, they behave differently in the calcium-uptake system. Another difference which we have observed is that chloramphenicol accelerates the rate of initial swelling, while oligomycin does not.

Table 2. INHIBITION OF CALCIUM UPTAKE BY DINITROPHENOL, ADP AND OLIGOMYCIN

Energy source		Inhibitor	Ca uptake (mμmoles/ mg N/10 min)
Substrate	ATP		
−	−	—	74
+	−	—	281
+	−	$1{\cdot}2\times10^{-4}$ M DNP	76
+	−	$2{\cdot}6\times10^{-3}$ M ADP	104
−	−	$2{\cdot}6\times10^{-3}$ M ADP	65
−	+	—	265
−	+	$1{\cdot}2\times10^{-4}$ M DNP	106
+	+	—	595
−	−	—	252
+	−	—	1,960
+	−	2 μg/ml. oligomycin	1,630
−	+	—	1,640
−	+	2 μg/ml. oligomycin	364

Mitochondria isolated and experiment conducted as previously described (ref. 1). Media for the upper experiment contained 625 μmoles sucrose, 12 μmoles $MgCl_2$, 0·25 μmoles $CaCl_2 + {}^{45}Ca$ and 17 μmoles phosphoric acid in a volume of 2·5 ml. with *p*H adjusted to 7·5 with *tris*. Energy source was 8 μmoles succinate and/or 6·5 μmoles ATP. Media for the lower experiment had in addition 0·6 μmoles NAD, 0·4 μmoles thiamine-pyrophosphate and 0·1 μmoles coenzyme *A*. Substrate was 40 μmoles pyruvate + 5 μmoles succinate.

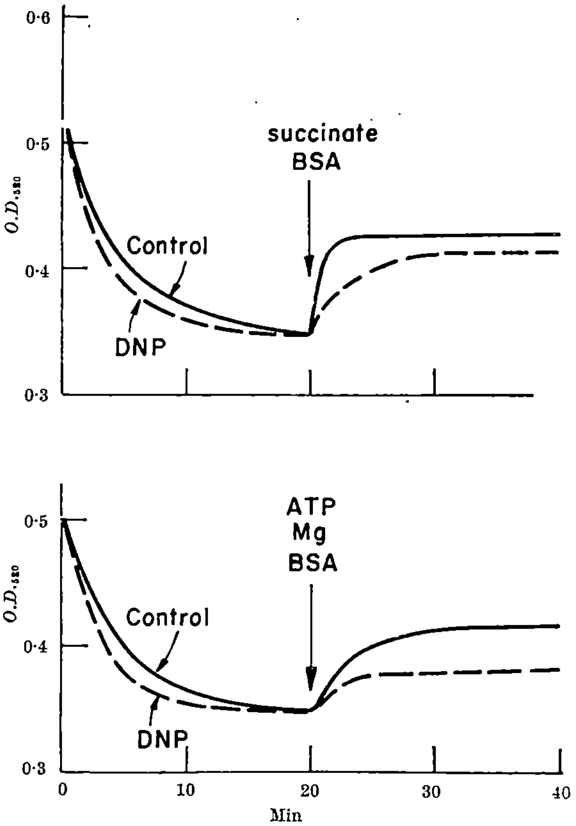

Fig. 1. Swelling and contraction of corn shoot mitochondria. Reaction started by adding 0·06 ml. of washed mitochondria in 0·4 M sucrose to 5 ml. of 0·2 M KCl + 0·02 M *tris* (*p*H 7·5) with and without 5×10^{-4} M DNP. Optical density changes at 520 mμ were followed in a Coleman model 11 spectrophotometer. Final concentrations of additives: 8 mM succinate; 5 mM ATP; 1 mM $MgCl_2$; 1 mg/ml. BSA (bovine serum albumin)

Substrate and ATP-powered uptake of calcium are inhibited by DNP (Table 2). Succinate-powered calcium uptake is inhibited by ADP, a result reported by Brierley *et al.*[6] for phosphate uptake. (Phosphate uptake accompanies uptake of calcium in these experiments.)

Both dinitrophenol and *m*-Cl-CCP enhance the ATPase activity of maize mitochondria (Heytler[12]); chloramphenicol does not (Fig. 2). At concentrations where all three agents begin to depress oxygen consumption (in parallel Warburg experiments), there is a depression of ATPase. With further increases in DNP or *m*-Cl-CCP concentration, there is a secondary rise in ATPase. Although the results are not detailed here, 1 μg/ml. oligomycin gives about 80 per cent inhibition of ATPase activity, which is comparable to the inhibition with animal mitochondria[13].

Oxidative phosphorylation by maize mitochondria is inhibited 50 per cent by approximately 2×10^{-4} M DNP,

Table 3. INHIBITION OF ATP-POWERED CALCIUM UPTAKE BY CHLORAMPHENICOL

ATP	Chloramphenicol	Ca content (mμmoles/ mg N)	ATP-powered Ca uptake (mμmoles/mg N)
−	—	108	—
+	—	415	307
+	2×10^{-3} M	276	168
+	4×10^{-3} M	184	76

Corn shoot mitochondria were isolated and experiment conducted as previously described (ref. 1), except that incubation time was 5 min. Medium contained 625 μmoles sucrose, 12 μmoles $MgCl_2$, 0·25 μmoles $CaCl_2 + {}^{45}Ca$, 17 μmoles phosphoric acid neutralized with *tris* (*p*H 7·5), 0·1 ml. ethanol, 6·5 μmoles ATP where indicated, and 0·456 mg mitochondrial nitrogen in volume of 2·5 ml.

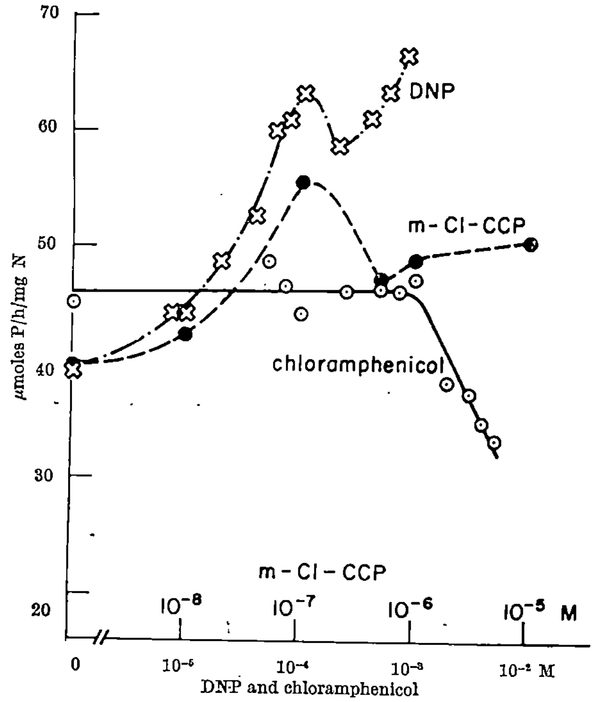

Fig. 2. ATPase activity of corn shoot mitochondria. Reaction at 28° C started by adding 0·1 ml. mitochondria (0·16–0·18 mg N) to 5 ml. of 0·2 M KCl+0·02 M *tris* (*p*H 7·5), 0·005 M ATP, 0·001 M $MgCl_2$ and uncoupler as indicated. Reaction terminated at 30 min with 5 per cent trichloroacetic acid, and change in inorganic phosphate from initial level determined. The ethanol added with the uncouplers was not sufficient to affect ATPase activity

0·08 µg/ml. oligomycin and 2 × 10^{-3} M chloramphenicol, using pyruvate-malate or pyruvate-succinate as substrate. These same concentrations suppress oxygen consumption by about 20, 40 and 20 per cent, respectively.

In all, we have examined four mitochondrial functions with three inhibitors; the results are summarized in Table 4. It is clear that chloramphenicol acts more like oligomycin than like DNP, the exception being that chloramphenicol inhibits substrate-powered uptake of calcium, while oligomycin does not. There is another distinction not indicated in Table 4 (cf. Tables 2 and 3); on a concentration basis, oligomycin is a much more effective inhibitor. Indeed, chloramphenicol is of interest here largely because of questions about its mode of action in stopping ion accumulation.

Table 4. SUMMARY OF EFFECTS OF INHIBITORS ON ENERGY-LINKED MITOCHONDRIAL PROCESSES

Inhibitor	Oxidative phosphorylation	ATPase	Contraction		Ca uptake	
			ATP	Succinate	ATP	Succinate
DNP	–	+	–	–	–	–
Oligomycin	–	–	–	0	–	0
Chloramphenicol	–	–	–	0	–	–

0, no effect; +, promotion; –, inhibition.

We have attempted an analysis of the action of chloramphenicol as compared with DNP and oligomycin by use of a modified 'Type *I*' scheme of high-energy intermediates (Fig. 3). The discussion of Boyer[7] proved very useful for this purpose, and the concept of reactive '*X*' and '*I*' groups on a common molecule has been adopted. There is no attempt to depict how the primary high-energy intermediate is formed, nor is any identification of the intermediate implied. The scheme simply provides a vehicle for examining the action of the inhibitors which is consonant with the observations summarized in Table 4.

The moiety shown as $\overline{X\,I}$ is assumed essential to the passage of electrons through 'coupling' sites. The first high-energy intermediate is $\overline{X \sim I}$. This state is considered to power directly contraction of maize mitochondria, for contraction requires neither phosphate nor magnesium, and indeed is inhibited by phosphate (Table 1).

The phosphate inhibition of contraction is considered to be due to depletion of $\overline{X \sim I}$ in a reversible reaction yielding $\overline{X\,I} \sim P$. The high-energy phosphate can be utilized in ATP formation or in phosphate (plus calcium) uptake (see Rossi and Lehninger[14] for comments on which ion is actively transported). The preferred pathway must be to ATP formation, for uptake of calcium is inhibited by ADP (Table 2).

Alternatively, ion accumulation may utilize the non-phosphorylated intermediate by a separate pathway (see the scheme of Slater *et al.*[9]). However, phosphate is essential to uptake of calcium in maize mitochondria; arsenate, chloride, and sulphate are ineffective; similar results are reported for uptake of magnesium by animal mitochondria[6]. Thus, any alternative pathway would also involve phosphorylation. For the sake of simplicity, a single phosphorylated intermediate is depicted.

Oligomycin is indicated to block the reversible transfer of phosphate between $\overline{X\,I} \sim P$ and ATP, much as in the scheme of Brierley *et al.*[6], and for the same reasons (Table 2).

The uncoupling action of DNP (and *m*-Cl-CCP) is deduced to be in the breakdown of the non-phosphorylated intermediate. Eisenhart and Rosenthal[15] recently concluded that DNP does not hydrolyse high-energy intermediates, but their pre-incubations included phosphate and presumably would have produced some phosphorylated intermediate which could phosphorylate ADP in the presence of DNP. Vignais[16], who preincubated in the absence of phosphate, concluded that DNP stimulates preferentially the hydrolysis of non-phosphorylated intermediates. With the present state of knowledge on high-energy intermediates, there seems to be no alternative which will explain the action of DNP in increasing the ATPase and the rate of swelling, and in inhibiting ATP-powered contraction and uptake of calcium. DNP clearly operates at the electron transfer side, yet it also functions to 'waste' energy channelled through from ATP. Some intermediate along the way must be affected in a fashion which will reduce the general level of intermediates available for osmotic work. Cleavage of the $\overline{X \sim I}$ bond would do this.

Within this frame of reference, the action of chloramphenicol can be examined. Chloramphenicol is not an uncoupler of the DNP type, for it does not inhibit substrate-powered contraction. It must therefore act beyond $\overline{X \sim I}$. It inhibits rather than promotes ATP hydrolysis, and blocks ATP-powered contraction, suggesting that it prevents $\overline{X \sim I}$ formation from ATP. Unlike oligomycin,

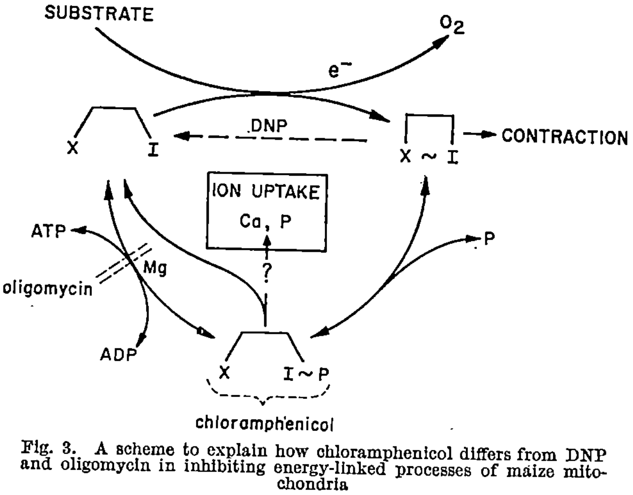

Fig. 3. A scheme to explain how chloramphenicol differs from DNP and oligomycin in inhibiting energy-linked processes of maize mitochondria

it will prevent substrate-powered uptake of calcium. In all, only one site is left to be involved; chloramphenicol in some fashion must block the formation or utilization of the phosphorylated intermediate.

This deduction, of course, is only as sound as the scheme, and it would be surprising if the scheme were correct in detail. However, until such time as the high-energy intermediates are known and their functions are described, little else can be done to localize sites of inhibitor action.

These experiments with chloramphenicol are with the high concentrations essential to inhibition of salt uptake. The inhibition of protein synthesis with lower concentrations is not necessarily related to the effect on mitochondria.

The work was supported by grants from the U.S. Atomic Energy Commission (*AT*/11-1/-790) and the U.S. National Science Foundation (*G*–16082).

Note added in proof. In order to simplify Fig. 3, we did not depict the action of the 'phosphate-collecting' enzyme which is thought to transfer phosphate from the intermediate to ADP[3].

$$\overline{XI} \sim P + E \rightleftharpoons \overline{XI} + E \sim P$$
$$E \sim P + \mathrm{ADP} \rightleftharpoons E + \mathrm{ATP}$$

We now observe that this omission gives the impression that oligomycin would block the ADP–ATP exchange, which is not always true (Huijing, F., and Slater, E. C., *J. Biochem.* (Tokyo), 49, 493 (1961); Wadkins, C. L., *Biochem. Biophys. Res. Comm.*, **7**, 70 (1962)). Oligomycin would presumably block the first reaction above, leaving the second to carry out the ADP–ATP exchange.

ENERGETICS OF THE ELECTRIC ORGAN

By Dr. R. D. KEYNES, F.R.S.

Université de Louvain, Belgium

It was pointed out in 1906 by Bernstein and Tschermak[1] that if the immediate source of energy for the discharge of the electric organ was a movement of ions down their concentration gradients, then by analogy with the adiabatic expansion of a gas the electric organ would be expected to cool down during its discharge by an amount equivalent to the electrical energy dissipated externally. They performed experiments on the electric organ of *Torpedo*, which they regarded as verifying their hypothesis, though the sensitivity of their thermocouple and air thermometer (used as a joulemeter) was not really great enough to furnish very convincing evidence. After this hopeful beginning, no further examination of the thermodynamics of the electric organ was made until Abbott, Aubert and Fessard reopened the question in 1958. Using thermistors to measure the temperature changes in pieces of electric tissue from *Torpedo* they showed that there was indeed a phase of cooling during or soon after the electric discharge, but this was preceded and followed by warming phases which made it difficult to decide exactly how the magnitude of the cooling varied as a function of external resistive load (R_e).

Over the past five years we have made a fairly detailed investigation of the temperature changes in the electric organs of *Electrophorus*, *Malapterurus* and *Torpedo*, using somewhat smaller thermistor beads (diam. 0·25 mm) than in the earlier work[2], mounted on 20-mm lengths of twin glass capillary tubing so that they could be inserted between the electroplates with a minimum of damage to the tissue. The beads were insulated electrically by embedding them in 'Araldite' resin or (better) lead glass. The thermistors were used in pairs, connected in the opposite arms of a d.c. Wheatstone bridge, and in the case of *Malapterurus* each thermistor lay in the centre of a sandwich of electric tissue made by cutting the organ into pieces about 13 mm × 30 mm and putting two pieces together as shown in Fig. 1*A* with the same orientation of their electroplates and the skin outermost. The main reason for working differentially with two sandwiches or slices of tissue was to provide compensation for resting temperature drift, which all the same prevented the making of any useful measurements until the temperature of the preparation had been allowed to settle down for at least an hour inside a thermally insulated box. An additional advantage of this arrangement was that the observations could readily be duplicated (as, for example, in Fig. 3) by connecting the circuits for electrical stimulation and recording alternately to the two preparations. Unbalance of the bridge was detected by means of a Kipp Stylo galvanometer connected to a photoelectric feed-back

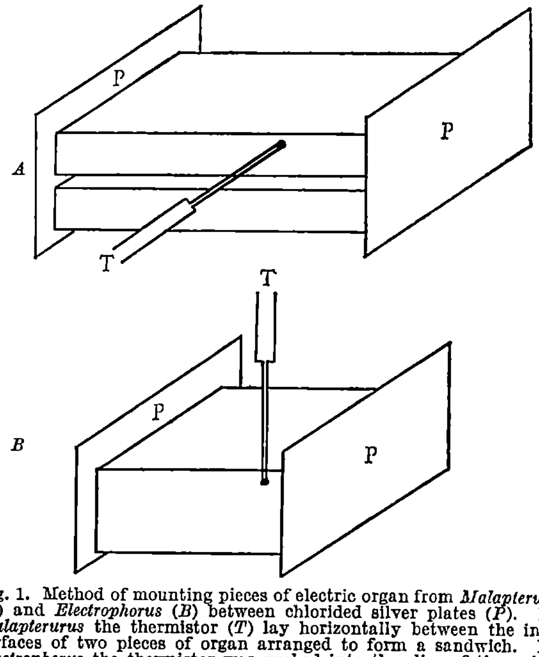

Fig. 1. Method of mounting pieces of electric organ from *Malapterurus* (*A*) and *Electrophorus* (*B*) between chlorided silver plates (*P*). For *Malapterurus* the thermistor (*T*) lay horizontally between the inner surfaces of two pieces of organ arranged to form a sandwich. For *Electrophorus* the thermistor was pushed into the slice of tissue in a direction parallel with the columns of electroplates through a nick in the the outer surface; the electroplates on either side of the thermistor were apt to be damaged in the process of insertion. When the electric discharge was generated, current flowed through the tissue between the silver plates, its size being governed by the value of the external resistive load connected across them

amplifier system as described by Hill[3], the output of which was displayed alongside the electric discharge on a Tektronix Model 555 double-beam oscilloscope and also on a high-speed (full-scale deflexion nominally 0·25 sec) Honeywell potentiometric recorder. The galvanometer response was speeded up by applying feed-back, and the overall time-constant for the thermistors and the galvanometer, tested with the thermistors inserted into uniform slices of agar jelly which were then abruptly warmed by a short pulse of current, was about 80 msec. The temperature coefficient of the resistance of each thermistor had been determined over a wide range of temperatures measured with a standard thermometer, and the records were calibrated by recording the deflexion corresponding to a known change in a standard decade resistance connected in parallel with a fixed resistance in one arm of the bridge.

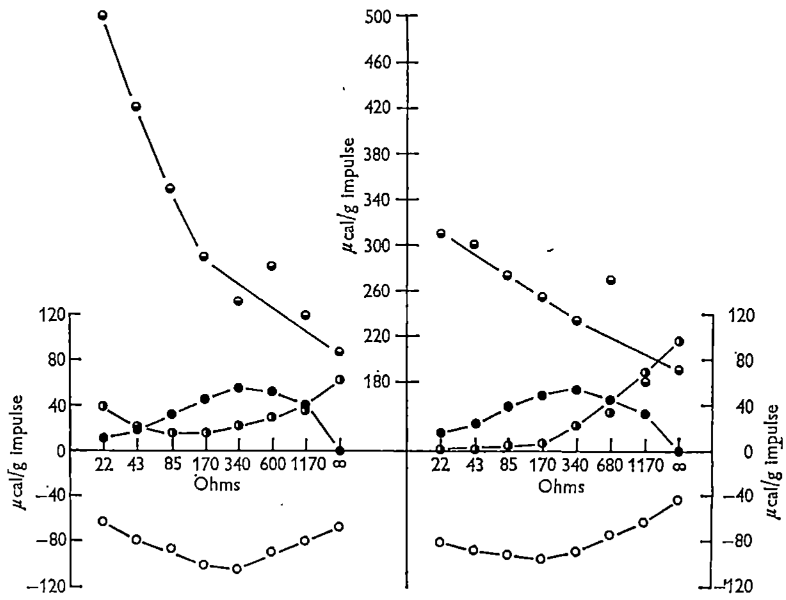

Fig. 3. Variation in the size of the thermal responses with external resistive load for two sandwiches of electric organ from a specimen of *Malapterurus*. ●, external electric work, measured with the microjoulemeter; ○, cooling phase Q_2; ◐, initial warming phase Q_1; ◒, recovery heat Q_3. Outer scales refer to work, Q_1 and Q_2; central scale is for Q_3. The measurements were made by reducing R_e in steps from infinity to 22 ohms, and then repeating the series in reverse order so as to be able to allow for fatigue by averaging the two values for each load. Recordings were made with 5 pulses at 10-msec intervals as for Fig. 2

Each sandwich or slice of electric tissue lay between two chlorided silver plates which were used for electrical stimulation (for *Electrophorus* and *Malapterurus*) and for application of the external resistive load. Trains of shocks of predetermined length (usually 5 pulses) and pulse interval (usually 10 msec) were generated by a programming device and applied to the tissue via a transistor switching circuit which was capable of delivering currents up to 1 amp without overloading during the shock, but the impedance of which as seen by the tissue at other times was very much higher than the selected loads. Corrections for the warming caused by the stimulus were sometimes necessary, but usually they were small; when working with *Torpedo* they could be avoided altogether by stimulating the nerve trunks rather than the tissue itself. Another important component of the apparatus was the joulemeter, which permitted direct measurements to be made of the external electric work performed during the discharge. This consisted of a resistance forming all or part of the load, which was wound round a small bundle of thermocouples connected to a galvanometer which registered their warming ballistically. It was calibrated by charging standard capacitances to known voltages and discharging them through the joulemeter. The joulemeter resistance was wound in sections switched so that its value could be changed by factors of 2 or 4; further variation of the load was achieved by connecting the joulemeter in series or in parallel with standard resistances.

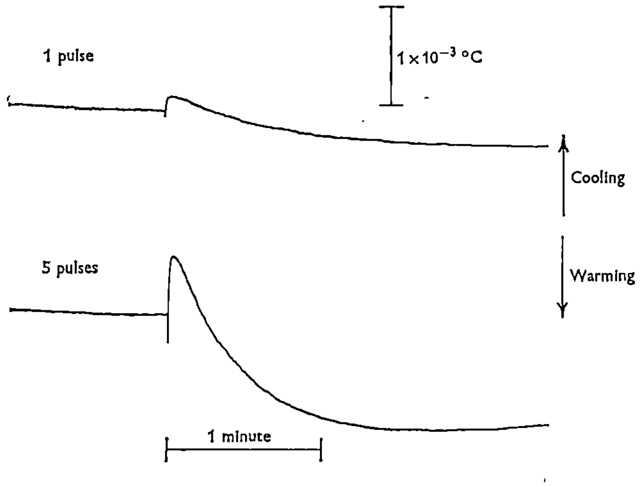

Fig. 2. Temperature changes in a sandwich of electric organ from *Malapterurus* after the application of 1 and 5 shocks. Shock strength was 16 V, duration 0·1 msec; even with 5 shocks, the warming due to the stimulus current alone was barely visible at this sensitivity. Temperature 19° C

Fig. 2 shows records of the temperature changes in a sandwich of tissue from *Malapterurus* in response to a single shock and to a train of five similar shocks spaced at 10-msec intervals. There was typically a very brief phase of warming which will be referred to as Q_1, then a more prolonged phase of cooling (Q_2), and finally a still more prolonged phase of warming (Q_3). For trains of up to 20 pulses there was a linear relationship between the peak amplitudes of Q_2 and Q_3 and the number of pulses, but since Q_3 was always the larger the summated value of Q_2 became relatively smaller for longer trains. Since each thermistor was placed in the thin layer of fluid and connective tissue separating the two pieces of electric organ which formed the sandwich, its most immediate surrounding was in effect a passive resistive element connected in parallel with the active elements (see Fig. 1*A*). The joule heat dissipated in such an element would be expected to be largest with the sandwich on open circuit ($R_e = \infty$), when the output voltage would be greatest. As may be seen in Fig. 3, the variation in size of Q_1 with R_e roughly fitted with what would be expected for a passive parallel element, and it hence seemed reasonable to interpret Q_1 as an artefact arising from the fact that the material nearest to the thermistor did constitute such an element. This interpretation was supported by the observation that in *Electrophorus*, where any damage to the electroplates while pushing the thermistors between them would give rise to a passive series element (see Fig. 1*B*), Q_1 was either absent (if such damage was slight) or only became conspicuous with low values of R_e. In *Torpedo*, where the electroplates are packed very closely together, it was difficult even with the smallest thermistors to avoid damaging the tissue so much that Q_1 became disconcertingly large; but in several of the most recent experiments records were obtained in which Q_1 was absent on open circuit.

The most interesting thermal event occurring at roughly the same time as the electric discharge was therefore the cooling phase Q_2. In the records shown in Fig. 2 it reached its peak with a time constant of about 250 msec; since the instrumental time-constant was only about 80 msec this might suggest that Q_2 actually took place slightly later than the electric discharge. However, the extra 170 msec might be accounted for by the presence of a passive layer of the order of 200µ thick on either side of the thermistor. Certainly there is a non-responding layer close to the thermistor, although this seems a rather high estimate for its depth. It is safest to conclude that Q_2 is either perfectly synchronous with the discharge or is not delayed after it by more than a fraction of a second. The average size of Q_2 on open circuit in *Malapterurus* at 20° C was 65 µ° C/impulse, and on loading the tissue electrically Q_2 increased to a maximum value of about 110 µ° C/impulse. The corresponding figures for *Electrophorus* at room temperature were 59 and 83 µ° C/impulse[4]. In *Torpedo* the open circuit and maximum values at 5° C were rather higher, 187 and 227 µ° C/impulse, but experiments on *Electrophorus* showed that Q_2 increased on cooling, so that all three species would have quantitatively similar values of Q_2 at room temperature.

When the size of Q_2 is plotted against R_e as in Fig. 3 and compared with the value of the external work performed at the same time, it is seen that in one respect Bernstein's prediction is fulfilled, since both Q_2 and the work attain a maximum at about the same value of R_e; in *Electrophorus* the maxima seemed to coincide less well, the value of R_e for greatest Q_2 being definitely smaller than for greatest work. The figures for the work fit very closely on to the theoretical curve for a constant-voltage generator with a fixed internal series resistance R_i, the condition for maximum power output being, of course, that $R_e = R_i$. However, it is clearly impossible to explain the results solely in terms of an adiabatic mixing process, since not only is there a substantial quantitative discrepancy between the maximum value of the cooling and the maximum external work when they are expressed in the same units (taking the specific heat of electric tissue as 0·87 cal/g), but also it is necessary to account for the appreciable cooling that takes place on open circuit, when no current flows in external circuits and the external work is zero. Our results seem best fitted by supposing that Q_2 is the sum of two components, one of which is fixed in size and is independent of load, and the other of which is the cooling predicted by Bernstein, equal and opposite to the external work. A possibility which can quickly be dismissed is that the open circuit cooling arises because there is always a leakage resistance round the edges of the slab of tissue which prevents true open circuit operation. It can readily be shown that such a resistance would have to be appreciably lower than the observed resting resistance of the whole tissue slice, and also very much smaller than the probable resistance of the thin inert layer of fluid outside the slice.

The Bernstein cooling arises, in effect, from the entropy change when work is done at the expense of the ionic concentration gradients. To the extent that the thermodynamic behaviour of the system is affected by changes in hydration of the ions with their concentration, a further heating or cooling of mixing would be anticipated, although this effect would be a second-order one. Unfortunately, the heat of mixing of Na^+ and K^+ is small and positive[5], and the only obvious way in which an extra cooling of mixing could be produced would be if the current flowing through the electroplates were carried by Na^+ ions entering the cells through one face (in *Electrophorus* the innervated posterior face[6], in *Malapterurus* the anterior face[7]) and by Cl^- ions entering through the opposite face rather than by K^+ ions leaving. The heat of dilution of sodium chloride, which is relatively large and is negative, might then be elicited in addition to the Bernstein cooling. However, the meagre electrophysiological evidence does not unequivocally support the idea that Cl^- ions may carry a large fraction of the current, and, in any event, such a mechanism would not explain the occurrence of open circuit cooling, when the only ionic movements are those necessary to alter the potential across the active face of the electroplate, which are almost certainly appreciably smaller than those that take place when large currents are drawn.

Another possible source of cooling would be an absorption of heat at the faces of the electroplates analogous with the Peltier effect. There seem to be two good reasons for rejecting this suggestion. In the first place, Peltier cooling during current flow only takes place at every other junction in a sequence of dissimilar conductors, there being an equal production of heat at alternate junctions, so that apart from joule heat the average temperature change over an even number of junctions is zero. Since the thermistors were large compared to the spacing of the electroplates, the temperature changes observed were certainly the average of those occurring at the opposite faces of each electroplate, and any Peltier cooling at one face would have been balanced by the corresponding warming at the other. Even if it were argued that in the electric organ the balance may not be exact because the current is carried by different ions through alternate faces, the Peltier analogy has to meet the further objection that any extra cooling attributed to it would be least on open circuit and would increase in proportion to the current drawn, instead of being independent of external load. The same objection applies to any explanation for the extra cooling which would make it vary with the total current flow, such as a hypothetical coupling of the ion transfer through the cell membranes to an endothermic chemical reaction. Thus, although some contribution from an effect similar to Peltier cooling is not excluded, the analogy seems unable to provide a complete explanation for the excess cooling.

A plausible further source of cooling which might meet the requirement of not varying greatly with external load would be the occurrence as an integral part of the permeability change in the active membranes of a process involving the melting or splitting of a membrane component. It would also be necessary to suppose that the restoration of the quiescent condition of the membrane at the end of the action potential did not simply take place through a direct reversal of the melting process, since, if it did, the net temperature change after each complete functional cycle of the permeability mechanism would merely be zero. This further condition means that the electroplate would have to have a reservoir of the component to be melted or split which was not instantaneously replenished after each impulse. The idea that the cell or the membrane contains a supply of a substance which is obligatorily consumed during electrical activity is, of course, contrary to recent evidence on the perfused squid axon[8], which is capable of conducting hundreds of thousands of impulses after replacement of virtually all its cytoplasm by a potassium sulphate solution, and in which the permeability mechanism seems likely to involve a completely reversible reorientation of charged dipoles within the membrane rather than the kind of process envisaged above for the electric organ. But the permeability mechanisms need not be assumed to be identical in these very different tissues. It may also be objected that the operation of the permeability mechanisms would be unlikely to have the same thermal consequences in all three types of electric fish considered here, since the active membrane in *Torpedo* is apparently strictly cholinergic and so exclusively chemically excitable[9], whereas *Malapterurus* is almost as exclusively electrically excitable[7], with *Electrophorus* in an intermediate position. Nevertheless, the open circuit cooling is roughly the same in each case. However, in the absence of any evidence as to the precise difference at the molecular level between chemical and electrical excitability, this argument is still not a decisive one. The suggestion that there may be some form of depolymerization in the membrane during the action potential has the further attraction that this might lead to osmotic effects which may be related to the changes in light scattering observed by Aubert, Chance and Keynes[10]. It is hoped that a more detailed comparison of the time-courses of the early thermal and optical effects will throw more light on this question.

Finally, the origin of the terminal phase of warming, Q_3, may be considered briefly. In *Electrophorus*[10] its time course is similar, both at room temperature and at 7° C, to that of the easily observed reduction and subsequent restoration of the size of the action potential which has been attributed to changes in the ionic concentrations within the electroplates, and its extent is roughly consistent with quantitative analyses of the breakdown of creatine phosphate[10,11]. Although similar evidence has not yet been obtained for *Malapterurus* and *Torpedo*, it is reasonable to assume that Q_3 arises from the operation of an ionic pump, driven by phosphate-bond energy, which restores the ionic concentration gradients the running down of which constitutes the immediate source of energy for the electric discharge. A still later recovery process, the activation of glycogenolysis to restore the phosphate potential, has been investigated in *Electrophorus* by optical[10,12] and chemical methods[11,13]. It takes place too slowly for any accompanying temperature changes to be readily separable from the dissipation of heat into the apparatus which inevitably follows its release as Q_3. As might be expected, the size of Q_3 increases steadily as R_e is reduced (Fig. 3) and as the downhill movement of ions in each impulse is correspondingly increased; this effect is more marked in *Malapterurus* than it sometimes is in *Electrophorus*.

These experiments were started in the Physiological Laboratory, University of Cambridge, with the help of grants from the Rockefeller Foundation, the Nuffield Foundation and the Department of Scientific and Industrial Research. We thank Mr. R. H. Cook and Mr. S. B. Cross for assistance in the construction of apparatus and the performance of experiments, and for the care with which they looked after the fish.

RECIPROCAL ACTIVATION AND INHIBITION OF CORTICAL NEURONES AND VOLUNTARY MOVEMENTS IN MAN: CORTICAL CELL ACTIVITY AND MUSCLE MOVEMENT

By DR. CHOH-LUH LI and DR. JOHN M. TEW, jun.
Surgical Neurology Branch, National Institute of Neurological Diseases and Blindness,
National Institutes of Health, Bethesda, Maryland

IN 1906, Sherrington[1] introduced a theory of reciprocal innervation on the basis that simultaneous excitation and inhibition of the agonistic and antagonistic musculatures are required for execution of smooth phasic movements. Particularly in view of recent observations on reciprocal excitation and inhibition of unit discharges recorded with microelectrodes from the retina[2,3] and receptive fields of the cerebral cortex[4-6], this theory may also be applied to the integrative action of the sensory system.

The reciprocal behaviour of units in the receptive fields—the visual cortex and somatosensory cortex—has been extensively examined, but there are relatively few reports of similar investigations on the motor cortex. It is known that, under certain experimental conditions, inhibition of neuronal activity in the motor cortex occurs[7,8]; as yet, this phenomenon has not been investigated in relation to phasic movements.

Cordeau *et al.*[9], in Jasper's laboratory, produced 'postural' tremors in monkeys. By recording with microelectrodes from the sensorimotor cortex, these authors found that some neurones discharged synchronously with the rhythmic tremor movements. Since these movements were involuntary and comparable to passive movements, questions were raised. Could the cortical unit discharges be the result of afferent stimulation? Did they represent the central pace-maker for tremor movements? It has been shown that passive movements of a contralateral limb evoke spike discharges from the somatosensory cortex[5] and that stimulation of a contralateral peripheral sensory nerve can elicit a response from cortical neurones which also respond to stimulation of the pyramid in the medulla[8]. These findings were obtained in experiments on animals and support the argument that the alternating cortical discharges recorded by Cordeau from tremoring monkeys may have represented responses to stimulation of peripheral sense organs.

This article concerns cortical unit activity related to voluntary contraction and relaxation in the fingers of patients operated on for epilepsy or Parkinson's disease. The selection of patients and the method of recording are being reported elsewhere[10]. In brief, the micromanipulator, microelectrode carrier, and pre-amplifier were mounted on a ring which was, in turn, attached to the skull over a trephine opening. The assembled equipment weighed 30 g and was 1·5 cm in diameter and 13·5 cm in height. Before use, it was sterilized at 140° F for 4 h in a gas chamber. The recording was carried out under closed-skull conditions which not only preserved the physiological state of the cortex but also prevented respiratory and pulsatory movements of the brain[11]. This made it possible to maintain the recording microelectrode in one position in reference to the cortical cell for a long period of time. During recording, the patient was under local anæsthesia and was able to converse with the attending physician.

When the microelectrode was placed in the precentral cortex and the unit discharges were recorded, the discharge-frequency was often altered by contraction and relaxation of the patient's contralateral fingers. It soon became apparent that when the patient closed his hand, an increase in activity of some cortical units with a simultaneous decrease in activity of other units occurred. At the same time, the discharge pattern of some other units remained unchanged. This was best illustrated in the case described here.

The patient was a sixty-year-old housewife suffering from severe hypokinesia, rigidity and fine tremors, all of

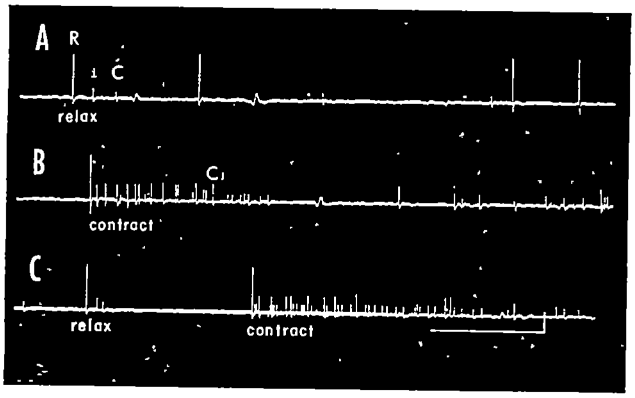

Fig. 1. Microelectrode recording from left precentral cortex of a conscious patient who intermittently relaxed and closed her right hand. The extracellular electrode recorded three units (*R*, *i* and *C*) in *A* and another (C_1) in *B* and *C*. *A*, *B* and *C* are continuous records. Upward deflexion represents positivity. Voltage calibration, 2 mV; time, 0·5 sec

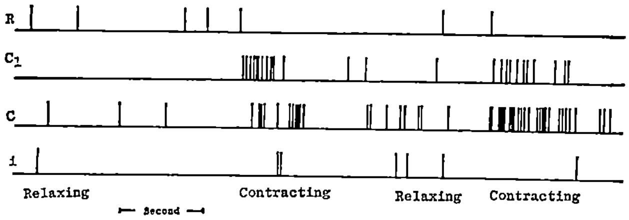

Fig. 2. The time relationship of the spike discharges from units *R*, *C*, C_1 and *i* during relaxation and contraction of the right fingers

which were most marked in the right upper extremity. Thalamotomy was carried out under local anæsthesia. Immediately following insertion of an electrode, presumably into the ventrolateral nucleus of the left thalamus, the tremor movements in the right hand ceased, However, there was still some rigidity in the arm. Microelectrode recordings from the left precentral gyrus showed that when the hand was closed, a burst of spike discharges occurred. When the right hand opened and closed in rapid succession, the recording shown in Fig. 1 was obtained.

Relaxation of the hand gave the tracing in *A* of Fig. 1. The amplitude of extracellular unit spike potentials varies with the distance between the recording electrode and the unit[11]. In this case, the extracellular microelectrode recorded spontaneous spike potentials of three different amplitudes; *R*, *i* and *C* were 3·1 mV, 1·0 mV and 0·66 mV, respectively. Thus, the extracellular electrode was recording spike activity from three units. It can be seen that during relaxation of the hand, the *R*-unit fired with an interspike interval ranging from 0·57 to 1·35 sec. The interspike interval of the *C*-unit potentials ranged from 0·7 to 0·9 sec. When the hand was closed (Fig. 1*B*), the *R*-unit stopped firing. Simultaneously, the *C*-unit discharged more rapidly, and the discharges occurred in bursts. In addition, a train of spike potentials was recorded from another unit (C_1-unit) which had been inactive during relaxation of the hand. When the hand was again relaxed, the previous activity pattern of the *C*-unit gradually resumed, the bursting discharges of the C_1-unit rapidly subsided and spike potentials of the *R*-unit reappeared. During this entire period, no significant change in the discharge activity of the *i*-unit was recorded. This unit was indifferent to movement of the fingers.

The discharge patterns of these four units (*R*, *C*, C_1 and *i*) are traced in Fig. 2. Since the number of cells under investigation was relatively small as compared with the cell population of the precentral cortex, no statistical treatment of the results in this investigation is possible. Nevertheless, the results clearly demonstrated that different cells in the precentral cortex behaved differently in connexion with voluntary movements. These movements were consciously motivated and were not involuntary. Therefore, it is proposed that reciprocal activation and inhibition of certain neurones in the motor cortex are necessary for contraction and relaxation of muscles in the execution of phasic movements. This is in keeping with Sherrington's theory of reciprocal innervation of agonistic and antagonistic musculatures.

EFFECT OF ŒSTRADIOL ON BONE MARROW TRANSPLANTATION IN LETHALLY IRRADIATED MICE

By Dr. JOHN S. THOMPSON, RICHARD W. REILLY*, HENRY P. RUSSE†
and Dr. ATTALLAH KAPPAS

Argonne Cancer Research Hospital‡ and Department of Medicine, University of Chicago

SEVERAL investigations have confirmed the observation by Treadwell *et al.*[1] that œstrogenic hormones afford some degree of radio-protection to sub-lethally irradiated mice. There is general agreement that either a single large injection or a 10-day course of œstrogen pretreatment offers maximal benefit. Mirand *et al.*[2] report some protection when œstrogen is instituted after X-irradiation, although other investigations[3,4] have demonstrated an increased mortality when hormone is administered during this period. It is well known that pharmacological amounts of œstrogens usually induce a progressive hæmatopoietic depression in dogs[5], but their influence on intact mice is much less striking[6,7]. Despite considerable examination, the mechanism of this hormonal phenomenon as well as that of œstrogen action on cellular elements of the hæmatopoietic and lymphoid organs remains unresolved[8,9].

Lethal irradiation followed by inoculation of bone marrow cells provide a means for investigating, in semi-quantitative circumstances, the influence of œstrogenic hormones on the proliferation and function of both hæmatopoietic and lymphoid cells. The purpose of this article is to describe the effects of pharmacological

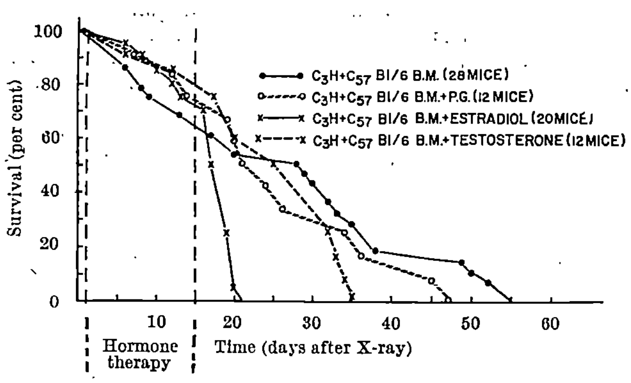

Fig. 1. The effect of œstradiol on the survival of lethally irradiated *C3H* mice injected with allogeneic *C57Bl*/6 bone marrow (*B.M.*)

amounts of œstradiol, administered to lethally irradiated mice receiving both syngeneic and allogeneic bone marrow and, in a separate set of experiments, administered to adult mice which served as bone marrow donors to lethally irradiated allogeneic hosts.

Twelve to sixteen week old *C3H/Anf* and *C57Bl*/6 female mice were used both as donor and host where indicated throughout the investigation. These mice were purchased from the Cumberland View Farms, Oak Ridge, Tennessee, and maintained on the 'Rockland Mouse Diet' and water *ad libitum*. The methods of irradiation, housing and feeding of animals were identical to those followed in previous investigations[10]. Irradiated mice received 900 r., in air X-irradiation, by means of a G. E. Maxitron-250 X-ray machine. Within 4 h of lethal irradiation 10 × 10^6 bone marrow cells suspended in Tyrode's solution were injected intravenously. Œstradiol and testosterone were dissolved in 10 per cent NNDMA (*N*,*N*-dimethylacetamide; Eastman Organic Chemicals, Eastman Kodak Corporation, Rochester, New York)[5] propylene glycol. A 0·1-ml. volume of solution containing 0·5 mg of hormone or the control vehicle was injected subcutaneously three times a week during the indicated treatment schedules. In those experiments in which the host was treated following lethal irradiation, the steroid and control injections were begun on the day after irradiation and bone marrow transplantation. These were continued for 2 weeks, during which time a total of seven injections was given. In the experiments in which bone marrow donor mice were treated, either three injections were given in 1 week or twelve injections were administered in a 4-week period. A daily record of animal death was maintained and expressed as percentage survival on any given day following radiation.

Fig. 1 indicates that œstradiol shortens the survival of lethally irradiated *C3H/Anf* mice given allogeneic *C57Bl*/6 bone marrow. Whereas this combination normally leads to 100 per cent mortality in 55 days because of a severe, progressive secondary disease syndrome, œstradiol treatment resulted in 100 per cent mortality by the twenty-first day after irradiation. Testosterone and control vehicle solutions appeared to have no effect on survival comparable to that seen with œstradiol.

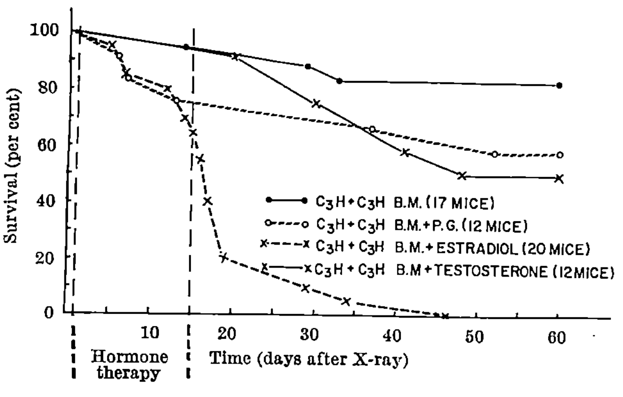

Fig. 2. The effect of sex hormones on the survival of lethally irradiated *C3H* mice injected with syngeneic *C3H* bone marrow (*B.M.*)

Fig. 2 reveals this pattern of accelerated death even more clearly in *C3H/Anf* mice given syngeneic *C3H/Anf* bone marrow. Within the 60-day period of observation only three of seventeen control animals which received neither hormone nor control solution injections died. Of those animals treated with œstradiol, 80 per cent had died by the nineteenth day and 100 per cent were dead by the forty-fifth day after irradiation and bone marrow transplantation. Testosterone and the control solution injections may have induced a modest reduction in survival, but the effect was not comparable to that of œstradiol.

Fig. 3 demonstrates the accelerated mortality of lethally irradiated *C3H/Anf* mice when donor bone marrow was obtained from *C57Bl*/6 mice which had been treated with œstradiol for 1 or 4 weeks. In this experiment, less than 50 per cent of the transplanted hosts were living 10 days after lethal irradiation and all were dead by 28 days in both groups.

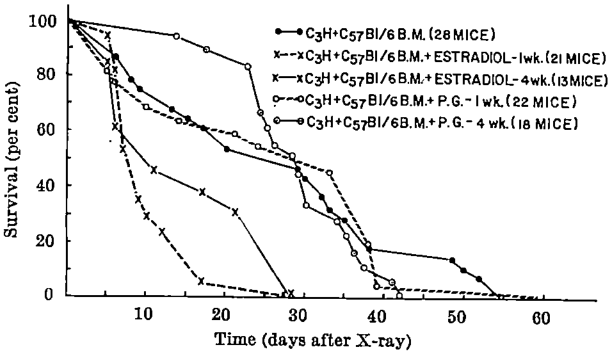

Fig. 3. The survival of lethally irradiated *C3H* mice transplanted with œstradiol-treated allogeneic *C57Bl*/6 bone marrow (*B.M.*); 1 and 4 weeks were time intervals of donor treatment with œstradiol or propylene glycol (*P.G.*)

Œstrogens regularly induce thymic involution, but their effect on other lymphoid organs is variable[9]. Although œstrogens may augment circulating antibody response to certain antigens[11], the results of Lurie[12] and more recently of Kappas *et al.*[13] indicate that these hormones also have a depressant effect on such manifestations of delayed hypersensitivity as cutaneous reactions to thyroglobulin and tuberculoprotein and the incidence of adjuvant arthritis in rats, a disorder shown by Waksman *et al.* to be of the delayed type[14]. These observations led us to consider the possibility that œstrogenic hormones might differentially affect various compartments of the lymphoid system.

Secondary or homologous disease, the wasting syndrome of delayed death following successful transplantation of genetically foreign bone marrow into lethally irradiated hosts[5], is thought to be an expression of immunologically competent cells. If œstrogens depressed the number or function of these cells, the survival of the mice injected with allogeneic bone marrow might be improved. The fact that œstradiol had a distinctly harmful effect when administered to lethally irradiated *C3H/Anf* mice given *C57Bl*/6 bone marrow and that the bone marrow transplant from œstradiol-treated allogeneic donors resulted in accelerated death of irradiated hosts tentatively discounts the selective suppression of these immunologically competent cells.

These experiments revealed an early pattern of death compatible with a primary failure of the transplanted cells to establish a successful graft when exposed to œstradiol before or after transplantation. Hæmatocrit and total leucocyte counts obtained 10, 15, 24 and 34 days after irradiation indicate that those mice treated with œstradiol remain leucopenic until death, whereas mice treated with testosterone or control injections showed a substantial rise of leucocytes by the fifteenth day. Since anæmia did not develop in any group, the observations suggest that under these experimental conditions œstradiol destroys leucocytes or their precursors and/or impairs the proliferation of leucocytic stem cells. Our results do not indicate whether this is a direct action on these cells or is mediated by an effect on other organ systems[9].

AMINO-ACID SEQUENCE AROUND THE REACTIVE THIOL GROUPS OF ADENOSINE TRIPHOSPHATE–CREATINE PHOSPHOTRANSFERASE

By Dr. A. R. THOMSON, J. W. EVELEIGH and B. J. MILES
Wantage Research Laboratory, Atomic Energy Research Establishment, Wantage, Berks.

THE phosphotransferases are a very important group of enzymes found in most, if not all, living cells. They catalyse the reversible transfer of 'high-energy' phosphoryl groups from a nucleoside triphosphate, usually ATP, to a substrate and have an absolute requirement for divalent metal ions[1], usually Mg^{2+} or Mn^{2+}. In addition, many of these enzymes require unmodified thiol groups for activity[2–5]. It is becoming increasingly likely that their reaction mechanisms are similar and that generally applicable principles are likely to emerge from an examination of individual enzymes of this group[6].

So far, very little is known of their chemical structure. This communication describes investigations into the chemical environment of the essential thiol groups of one of these enzymes, ATP–creatine phosphotransferase (CPT).

Creatine phosphotransferase catalyses the reaction:

$$\text{creatine} + \text{ATP}^{4-} \overset{\text{Mg}^{++}}{\rightleftharpoons} \text{creatine phosphate}^{2-} + \text{ADP}^{3-} + \text{H}^{+}.$$

The enzyme has been highly purified and crystallized[7], and has a molecular weight of 81,000 (ref. 8). It contains 6–7 free thiol groups/mole[9–11], two of which react rapidly and irreversibly with alkylating agents such as iodoacetate (and iodoacetamide)[2,3]. Loss of enzymatic activity can be exactly correlated with alkylation of these two thiol groups[2,3], both of which react at precisely the same rate[3]. The remaining thiol groups react only after denaturation. The enzyme is protected against iodoacetic acid-inhibition by its substrate equilibrium mixture[3,12]. These and other data strongly suggest that the reactive thiol groups are directly involved in catalysis, and although not involved in binding of substrates are close to the substrate binding sites[3,12–14].

In the present investigation we have used ^{14}C-iodoacetate to label the reactive thiol groups of CPT, thus enabling the peptides derived from these parts of the enzyme to be characterized (see also refs. 15 and 16). The presence of the radioactive label proved invaluable in the subsequent isolation of the peptides and also in the determination of their structure.

Labelling of enzyme. CPT was purified to the pre-crystallization stage by method *B* of Kuby *et al.*, and had a specific activity of 70–80 units/mg[7]. The absence of contaminating peptides was shown by treatment with FDNB (fluorodinitrobenzene)[17]. The enzyme contained 6–7 free thiol groups/mole, as determined both by conversion to *S*-carboxymethyl-cysteine (CMCys)[18] and by reaction with DTNB (dithio*bis*(nitrobenzoic acid))[31]. In the absence of urea, 1·5–2·0 thiol groups reacted with iodoacetic acid under the conditions later used for labelling. Labelling of the enzyme with 2-^{14}C-iodoacetic acid was carried out as follows[19]: CPT ~ 50 mg/ml.; 2-^{14}C-iodoacetic acid, 2 moles/mole CPT; *p*H 9·0 (0·1 M glycine): temperature, 30° C. After 40 min, when negligible enzymatic activity remained, solid urea was added to bring the solution to 8 M, and the enzyme was further alkylated with inactive iodoacetate (4 times molar excess over thiol groups). This avoided oxidation of any remaining thiol groups, and prevented possible disulphide exchange reactions during purification. After a further 3 h at 30° C, the reaction was terminated with mercaptoethanol, and low molecular weight compounds were removed by exhaustive dialysis.

Purification of tryptic peptides. The fully alkylated CPT was then digested with trypsin (2 per cent w/w), in a *p*H-stat at 30° C for 1 h. (The trypsin had been predigested in N/16 hydrochloric acid to minimize chymotryptic activity[20].)

The tryptic peptides were purified by ion-exchange chromatography successively on columns of 'Dowex-50–X2' and 'Dowex-1–X2' at 37° C. The gradients and conditions were essentially those of Konigsberg and Hill[21] for 'Dowex-50', and of Schroeder *et al.*[22] for 'Dowex-1'. The column eluates were monitored continuously for radioactivity with a scintillation plastic flow cell (Nuclear Enterprises, Edinburgh), and the collected fractions with ninhydrin using a modified auto-analyser technique. Typical chromatograms are given in Figs. 1 and 2; the latter shows the purification on 'Dowex-1' of the major radioactive peptide from the 'Dowex-50' run. Buffer salts were then removed by passage through a column of 'Sephadex *G*-25'. In different preparations *T*5 accounted for 45–50 per cent of the protein-bound radioactivity, *T*1 for ~ 10 per cent and *T*3 for ~ 9 per cent. (See Fig. 1 for numbering of peptides.)

Structure of T5. Hydrolysis (105° C, 6·5 N hydrochloric acid 18 h) and quantitative amino analysis gave the following composition for *T*5 (the assumed residues/mole are given in parentheses):

S-Carboxymethyl-cysteine	0·71 (1)	Proline	1·75 (2)	Leucine	3·80 (4)
Aspartic acid	2·14 (2)	Glycine	4·27 (4)	Tyrosine	1·00 (1)
Threonine	1·86 (2)	Alanine	1·19 (1)	Phenylalanine	1·06 (1)
Serine	1·03 (1)	Valine	0·88 (1)	Histidine	2·16 (2)
Glutamic acid	1·14 (1)	Methionine	0·97 (1)	Arginine	1·05 (1)

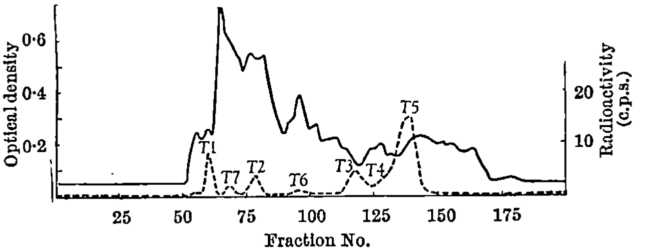

Fig. 1. Chromatogram of a tryptic digest of carboxymethylated-CPT on a column of 'Dowex-50-*X*2' (100 cm × 2 cm) with pyridine-formate and -acetate buffers. ——, Ninhydrin colour; - - -, radioactivity

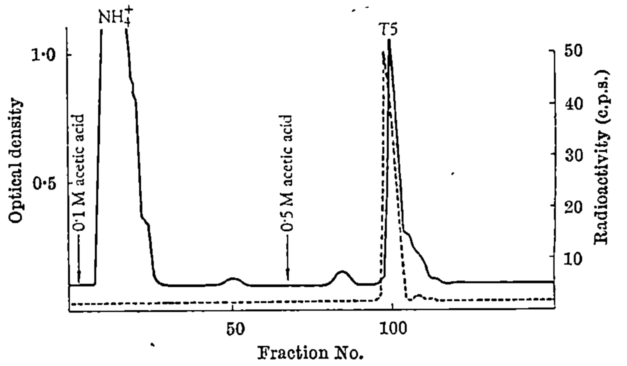

Fig. 2. Purification of *T*5 (Fig. 1) on a column of 'Dowex-1-*X*2' (150 cm × 0·9 cm) with α-picoline-acetate buffers. ——, Ninhydrin colour; - - -, radioactivity

End-group analysis by the Edman technique[21] indicated that the peptide contained only minor contaminants and showed alanine to be N-terminal. Also, virtually all the radioactivity was present as *S*-carboxymethyl-cysteine. To obtain smaller peptides more amenable to sequence analysis, *T*5 was digested with chymotrypsin (0·001 per cent, 1 h, 25° C) and the resulting peptides were separated on 'Dowex-50-*X*2' (50 × 1 cm) (Fig. 3). Peptide *C*1, which contained virtually all the radioactivity of *T*5, was then digested with pepsin (0·1 per cent, 16 h, 25° C) and separation of peptides was again carried out on 'Dowex-50-*X*2' (Fig. 4). Where necessary, further purification of peptides was carried out by electrophoresis at *p*H 2·0, 60 V/cm, 1 h.

The structures of the various peptides thus isolated were determined mainly by quantitative subtractive Edman degradation[21] and extensive use was also made of digestion with carboxypeptidase *A* and leucine aminopeptidase. The Edman technique was modified in that the cleaved peptides were purified, usually after every second step, by electrophoresis at *p*H 2·0, instead of by the column chromatographic method of Konigsberg and Hill[21]. Serine, glutamine and asparagine were distinguished by semi-quantitative electrophoresis at *p*H 2·0 since these amino-acids occupy the same position on the amino-acid analyser.

The data on which the structure of *T*5 is based are given in Table 1. It will be noted that the sequence of *C*4 has not yet been completed. Of the peptic peptides only *P*6 (yield ~ 15 per cent) is not consistent with the structure of *C*1, since on hydrolysis with acid it yields 1 mole of valine and 2 of leucine, and is not a mixture of valyl-leucine + leucine. Nevertheless, digestion of *C*1, from which it is derived, with leucine amino-peptidase yields 1 mole each of valine, leucine and threonine/mole *C*1. These points are still under investigation. (It should be noted that peak *C*2 (Fig. 3) consisted mainly of ammonium salts, together with a small amount of oxidized *C*1.)

The tryptic peptides *T*1 and *T*3 (Fig. 1) were also purified on 'Dowex-1-*X*2' as for *T*5. Amino-acid analysis of hydrolysates of these peptides, and end-group assays, indicated that *T*1 was probably *C*1 and *T*3 was probably *C*4 + *C*1, that is, they were derived by chromotryptic splitting of *T*5. This is not surprising in view of the susceptibility of the phenylalanine–methionine, and tyrosine–valine bonds to chymotrypsin already noted (Table 1).

The yield of peptides *T*5 (~ 47 per cent) together with its derivatives *T*1 (~ 10 per cent) and *T*3 (~ 9 per cent), a total of ~ 66 per cent of the protein-bound carbon-14 (actually ~ 80 per cent of the carbon-14 recovered as peptides), indicates that the chemical environment of the two essential thiols in CPT is identical. This strongly supports the view, based on kinetic evidence[3] and on substrate-binding experiments[23], that the enzyme contains two identical catalytic sites/mole each with one thiol group.

The enzyme contains eight half-cystine residues/mole and between 6 and 7 free thiols/mole[10,11]. Is the molecule then a dimer joined by a disulphide bond ? The available evidence suggests that it is not, since:

(1) Reduction followed by alkylation with iodoacetate yields 6·7–7 moles *S*-carboxymethyl-cysteine/mole CPT[10,11]. It cannot be excluded, however, that CPT contains a disulphide bond peculiarly resistant to reduction.

(2) No difference in molecular weight between native and reduced, fully alkylated CPT is detectable on 'Sephadex *G*-75' columns[11].

(3) Treatment with carboxypeptidase *A* indicates only one polypeptide chain in CPT[24]. (Digestion with carboxypeptidase *B* has yet to be carried out.)

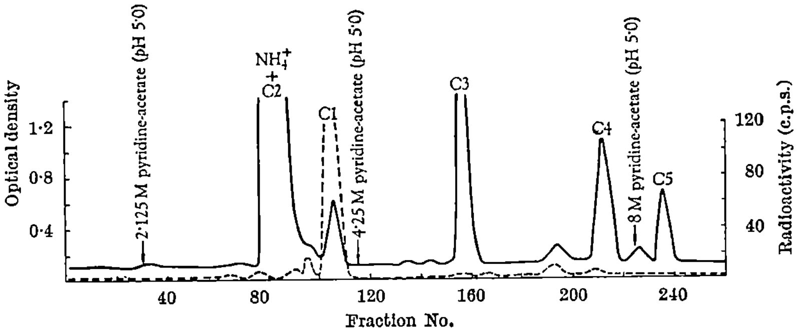

Fig. 3. Chromatogram of a chymotryptic digest of *T*5 on 'Dowex-50-*X*2' (150 cm × 1 cm) with pyridine-acetate buffers. ——, Ninhydrin colour; - - -, radioactivity

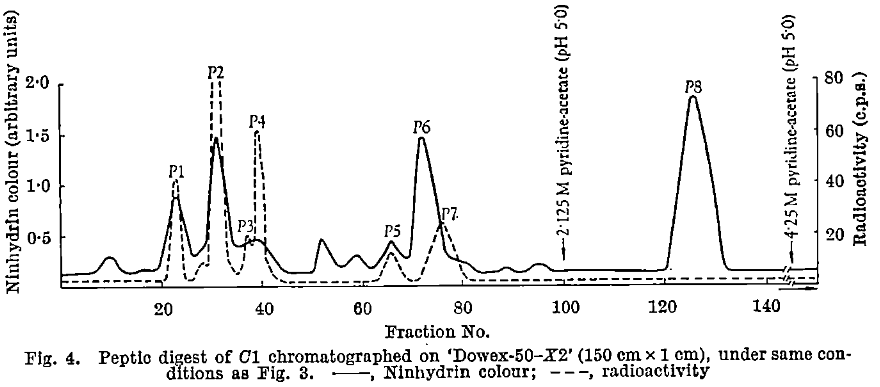

Fig. 4. Peptic digest of *C*1 chromatographed on 'Dowex-50-*X*2' (150 cm × 1 cm), under same conditions as Fig. 3. ——, Ninhydrin colour; - - -, radioactivity

Table 1

P8 gly–thr–gly–leu–arg

*CMCys, *S*-carboxymethyl-cysteine; ⇀, Edman degradation; --⇀, Leucine amino-peptidase; ↽, Carboxypeptidase *A*.

On the other hand, peptide mapping of trypsin hydrolysates of the enzyme shows only about half the expected number of ninhydrin-positive spots. It seems highly probable, therefore, that CPT contains two identical active sites per molecule each with one thiol group. It is unlikely, however, on the present evidence, to consist of two polypeptide chains linked by a disulphide bridge, although the molecule appears to be in the form of two parts of essentially similar composition. Possible explanations of the data are that CPT is a cyclic molecule with a protruding C-terminal chain (for example, ovalbumin[25]), or alternatively is a dimer linked by a peptide or other bond. Further work is obviously required to resolve this point.

The most notable feature of *T*5, the peptide containing the essential thiol groups of CPT, is the presence of proline C-terminal to these thiols. This is the first report of such a sequence in a 'sulphydryl' enzyme and it seems reasonable to assume that, since this amino-acid is a 'misfit' in the protein α-helix, its occurrence in this position is of considerable significance. Whether its role goes beyond that of conferring a particular configuration at this point in the polypeptide chain cannot be decided at this stage.

One of the characteristics of CPT and several other 'sulphydryl' enzymes (for example, arginine kinase[5], yeast alcohol dehydrogenase[26] and phosphoglucomutase[27]) is the unexpected finding that the reactivity of their essential thiol groups to iodoacetate does not vary between *p*H 6 and 10. This has led to the suggestion that these thiol groups are hydrogen bonded to basic groups on the protein, probably imidazole (cf. ficin[28]), and, on this basis, Rabin and co-workers have proposed reaction mechanisms for CPT[12] and yeast alcohol dehydrogenase[26]. An obligatory condition for this mechanism to operate is the presence of histidine adjacent to the reactive thiol group at least in the three-dimensional structure of the protein. Evidence in support of this mechanism has come from the recent isolation by Harris of a peptide containing the 'active centre' thiol groups of yeast alcohol dehydrogenase[29]. The fact that this peptide contains the sequence –val–cys–his– is therefore very significant, and the dissimilarity between this sequence and that of the corresponding one in glyceraldehyde-3-phosphate dehydrogenase (GPDH)[16], namely:

–ser–cys–thr–thr–asn (asparagine)–

which might be expected to be similar (cf. proteinase and esterases[30]) is of great interest. The effect of *p*H on the reactivity of the thiols in GPDH to iodoacetate has not yet been investigated.

In *T*5, histidine is not adjacent to the reactive thiol groups. The absence of such an obvious association in *T*5 does not, however, preclude its existence in CPT, since folding of the polypeptide chain of the enzyme (which contains 33 histidines) might well lead to the formation of such a thiol–imidazole pair.

Whether there is any evolutionary significance in the similarity between the sequences round the reactive thiols in GPDH (see foregoing) and in CPT:

–thr–cys–pro–ser–asn–

both obtained from rabbit muscle, cannot yet be decided.

In view of the similarities in the properties of the phosphotransferases, comparative investigations are being carried out on other enzymes of this group, together with more detailed investigations on creatine phosphotransferase.

Full details of the work briefly described here will be published elsewhere.

We thank Mr. S. G. Milsom, Mrs. E. W. Tripp and Mr. J. F. Laws for their assistance.

Note added in proof. With the use of carboxypeptidases *B* and *A*, it has been confirmed that the C-terminal sequences in *T*5, *T*1 and *T*3 are identical, namely, -gly-leu-arg.

SEGREGATION OF RADIATION-INDUCED MUTATIONS IN *Escherichia coli*

By DR. R. J. MUNSON and DR. BRYN A. BRIDGES
Medical Research Council Radiobiological Research Unit, Harwell

IT is now accepted[1] that the genetic material of bacteria is composed of two main sub-units or strands each of which is conserved during replication. Some years ago Witkin[2] reported that with rare exceptions a single nucleus of *Escherichia coli* contained a single unit of the *lac* gene mutable by ultra-violet light, that is, all progeny of a mutated nucleus carried the mutant gene. In a small proportion of cases, however, segregation of both mutant and non-mutant progeny from a single nucleus was observed. This could not at the time be satisfactorily explained. Recent advances in our knowledge of the structure and replication of the bacterial chromosome[1] provide two possible explanations. The wave of replication might have already passed the *lac* gene at the time of irradiation in those nuclei or alternatively mutations might have been induced in a single strand of the chromosome. It is conceivable that all the mutations yielding pure mutant progeny were in fact induced on only one strand of the chromosome. If, for example, the lethal and mutagenic action of ultra-violet light occurred independently in single strands of genetic material, then with only $\sim 0·1$ per cent of cells surviving, the probability that a mutated strand would be accompanied by a viable sister strand would also be $\sim$ 0·1 per cent. Thus in most cases colonies of purely mutant progeny should have appeared, and this Witkin found.

In some recent experiments with ultra-violet light[3], phosphorus-32 (ref. 4), and nitrous acid[5], massive doses of mutagen have also been used with attendant high lethality and consequent ambiguity in interpretation. In our experiments with the tryptophan requiring (try$^-$) strain *WP*2 of *Escherichia coli** we have been able to follow the segregation of prototrophic revertants induced by relatively low doses of X- or γ-rays which resulted in more than 80 per cent of the bacteria surviving. Two factors which made these experiments feasible were the ease of detection of mutants and the low spontaneous reversion rate in this strain, approximately 10^{-10} per generation time[6]. Preliminary results with this system at 22° have been reported elsewhere[7]. The experiments recorded here indicate that the number of mutable units per nucleus, derived from the average numbers of mutable units and of nuclei per bacterium, depends on the temperature.

Nuclear-stained preparations of bacteria at the time of irradiation were prepared by the method of Robinow[8] modified to the extent that air-dried films were used and acid hydrolysis was continued for only 5 min at 55°–60°. Preparations were examined visually using a times 90 objective and a blue minus filter. Our chief problem was whether our staining procedure enabled us to detect a nucleus as having divided at the precise time that division actually occurred. If, for example, nuclei did not appear to have divided until some while after that event, then the observed mean nuclear number for the population would be an underestimate of the true number. To investigate this possibility we allowed non-replicating, mainly uninucleate cells[9] to replicate their nuclei synchronously at 37° on addition of fresh nutrients, and followed the sequence of events with concurrent nuclear stain preparations and DNA determinations[10]. It was observed that most nuclei divided synchronously at a time close to that at which the DNA in the culture had doubled. It therefore seems that our staining procedure gives a value for the mean nuclear number which is unlikely to be affected by any significant systematic error.

Segregation of mutable units. The determination of the number of mutable units per bacterium involved a comparison of the frequency of induced revertants in a growing population of bacteria immediately after a short irradiation, that is, before any segregation of mutated mutable units had occurred, with the frequency a few generation times later when mutant segregation was complete. When the number of mutable units per bacterium is 1, 2, 2^2, 2^3.... it may be seen from Table 1 that the initial frequency is greater than the final frequency by a factor equal to the number of mutable units per bacterium and this is generally true for any such number *p*.

Table 1

Time after induction	0		τ		2τ		3τ		After segregation
Total No. cells	N		2N		4N		8N		
Mutant cells / Mutable units per cell	No.	freq.	No.	freq.	No.	freq.	No.	freq.	freq.

2	$2m$	$2m/N$	$2m$	m/N	$4m$	m/N	$8m$	m/N	m/N
4	$4m$	$4m/N$	$4m$	$2m/N$	$4m$	m/N	$8m$	m/N	m/N
.	.	.							.
.	.	.							.
.	.	.							.
p	pm	pm/N							m/N

The theoretical segregation pattern for induced mutations in cells containing 1, 2, 4 .... *p* mutable units. The mutant frequency in a very large population *N* is m/N per mutable unit at zero time. The population, numbers of mutants and their frequency at intervals of one generation time (τ) are shown and also the final mutant frequencies.

The segregation of mutable units in *Escherichia coli* *WP*2 was followed after short X-ray exposures (less than 5 min) of cultures in the process of exponential growth under full aeration. A turbidostatic system automatically controlled the addition of fresh glucose-salts minimal medium[6] plus 6 µg/ml. tryptophan, so that the optical density of the culture was kept constant to within ± 2 per cent. The usual volume of the culture was 300 ml. and the population density approximately 10^8/ml. Samples were removed from the flask or the overflow at intervals and assayed for numbers of mutants, viable bacteria, and total bacteria using a Hawksley Thoma counting chamber. Prototrophs (on 'Millipore' filters[6]) and auxotrophs were scored on minimal agar plates with 0·75 µg/ml. of tryptophan supplement. These plates allowed full expression of mutations, the number of colonies being independent of whether the mutant character was inherited by all daughter cells or only appeared in those arising from one nucleus or one mutable unit. Fig. 1 shows the results of a typical segregation experiment at 16°. Results from a number of such experiments at different temperatures are summarized in Table 2.

---

* The synthesis of tryptophan is blocked at an early stage in this strain and the *try* gene referred to does not correspond to that determining tryptophan synthetase production.

Table 2. MUTATION RATES WITH STANDARD ERRORS AT DIFFERENT TEMPERATURES

Temperature	Mutation rate per rad: Per nucleus (× 10⁻¹¹)	Mutation rate per rad: Per mutable unit (× 10⁻¹¹)	Mutable units per nucleus: From ratio of mutation rates	Mutable units per nucleus: From segregation experiments	Mutable units per nucleus: Weighted mean
37°	6·55 ± 0·45	3·89 ± 0·18	1·68 ± 0·15	1·28 ± 0·20	1·5 ± 0·2
22°	4·1 ± 0·37	2·42 ± 0·20	1·70 ± 0·22	1·68 ± 0·38	1·69 ± 0·22
16°	2·33 ± 0·10	1·13 ± 0·17	2·06 ± 0·35	2·23 ± 0·51	2·13 ± 0·31

Only a small transitory inhibition of growth occurred after irradiation with the doses of 1–2·5 krads used in these experiments[6]. Slight temporary increases in cell-length and nuclear number were also observed presumably due to a temporary inhibition of cell division.

An alternative approach to the problem of estimating the number of mutable units per nucleus is to measure in different exponontially growing cultures the induced mutation rate per nucleus before segregation occurs and in other cultures the mutation rate per mutable unit after segregation is complete. The mutation rate per nucleus was derived from observations of mutant frequency in suspensions of log phase *E. coli WP*2 irradiated under aeration in minimal medium without glucose or tryptophan. Suspensions containing ~ 6 × 10⁹ bacteria/ml. were exposed to a range of X-ray doses and 0·1 ml. aliquots plated at once on the usual minimal agar with 0·75 μg/ml. tryptophan supplement. Stained preparations for nuclear counts were also made at the time of irradiation. When the observed frequency of induced revertants divided by the average number of nuclei per bacterium and by the radiation dose was plotted against dose, the graphs in Fig. 2 were obtained. These curves, each derived from at least three independent experiments, can be regarded as survival curves for those organisms which ultimately give rise to mutant colonies, provided the induction of mutants is proportional to the radiation dose, a condition apparently satisfied over the range studied here although not under other experimental conditions where lethality is great[11]. The zero dose extrapolate of the line, which appears straight when plotted semi-logarithmically, is the induced mutation rate per nucleus per rad. Values of these mutation rates are given in Table 2. The temperature-dependence which is evident from these results is partly associated with the temperature immediately after irradiation. Further experiments are in progress and will be reported elsewhere.

The mutation rate per mutable unit was determined in continuous cultures which were controlled turbidostatically and grown under continuous gamma irradiation[6]. The irradiations lasted many generation times and the mutant frequency increased at a constant rate except during the first one or two generation times. The constant rate of increase was a measure of the mutation rate after full segregation, that is, of the mutation rate per mutable unit[6] (Table 2). Knowing the dose rate, the mutation rate per mutable unit per rad was readily obtained. The results at the three temperatures are included in Table 2.

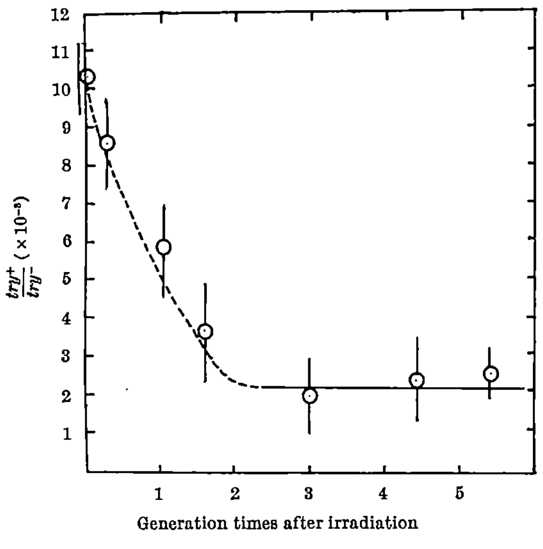

Fig. 1. Fall due to segregation in proportion of newly induced prototrophs in a population (mean nuclear number = 2·1) of *E. coli WP*2 growing exponentially at 16°. Vertical lines represent standard errors

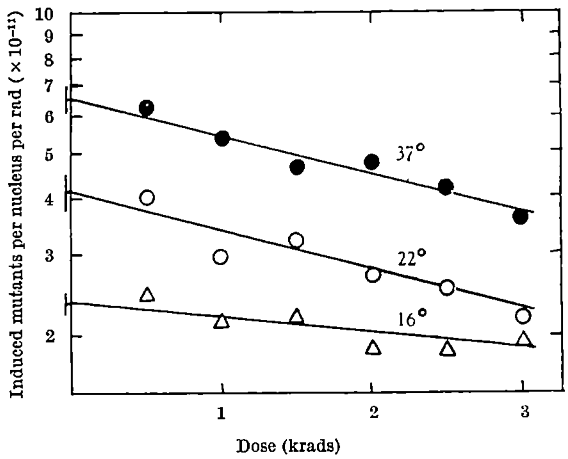

Fig. 2. Induced mutation rate per nucleus versus dose of 250-kV X-rays at different temperatures. Temperatures maintained throughout at values shown until 24 h after irradiation when plates at 16° and 22° were transferred to 37°. Vertical lines show standard errors of zero dose extrapolates

The estimates of numbers of mutable units per nucleus obtained by the two methods described here are in satisfactory agreement at 16° and 22°. At 37° there is a barely significant difference between the two estimates, but the trend to lower values with increasing temperature appears to be real.

Nature of the mutation event. Although it would be very premature to attempt to interpret the results of these experiments in terms of a general hypothesis relating to the primary events in mutation induction by radiation, some support for hypotheses already advanced by others is now apparent. The work of Deering[12], Kada, Brun and Marcovich[13] and Munson and Jeffery[6] has shown that with small X-ray doses the frequency of induced revertants of *E. coli WP*2 is proportional to the dose. Also experiments carried out by Deering[12] with particles of different LET showed a fall in mutagenic efficiency only at an LET greater than 190 MeV cm²/g. These observations suggest that the majority of mutants arise as the result of the passage of a single electron through or very close to that part of the DNA which corresponds to the mutable unit for this mutation. An analysis of Deering's LET data by the track segment method of Howard-Flanders[14], assuming a mutation rate of 4 × 10⁻¹¹/rad/mutable unit, shows that the sensitive region within which the production of one ion cluster induces a mutation with a probability of approximately unity is ~ 5 × 10⁻⁸ cm across. This would represent a rather small part of a nucleotide. It is interesting that Demerec and Sams[15] reported comparable X-ray reversion rates for three other auxotropic strains of *E. coli*. The hypothesis that a single ionization or cluster must be produced within one of a very few nucleotide pairs to cause a reversion does not appear on this evidence to be implausible.

The average number of genes of a particular locus to be expected in the nuclei of exponentially growing cells would depend on the mode of replication of the bacterial chromosome, and this is still subject to some uncertainty. If replication proceeded in a fixed linear order from a fixed point on the chromosome, the average number of *try* genes per nucleus would depend on the position of the *try* gene. An average of one gene per nucleus would imply a position at the end of the order and two genes per nucleus a position at the beginning. For all genes the average would be 1/ln 2, that is 1·44. Other replication models, for example, a fixed linear order but commencing at one of several points on a circular chromosome, or a fixed point of origin but proceeding in either direction round a circular chromosome, would give an average of approximately 1·4–1·5 genes per nucleus for all loci. Such models are, however, inconsistent with a strict interpretation of the results of Meselson and Stahl[16]. This difficulty could be overcome if it were postulated either that the probability of replication in one cycle beginning at a different point from that in the previous cycle is small but finite or that replication from a fixed point occasionally reverses its direction. Such small departures from strictly semi-conservative replication might not be detected in short-term experiments such as those of Meselson and Stahl, but would nevertheless have a sufficiently large randomizing influence over many generation times in a population to bring the average number per nucleus of every gene close to 1·44 and account for Nagata's[17] findings with an F^- strain of *Escherichia coli.*

Owing to our ignorance of the replication order in *Escherichia coli WP*2 the results in Table 2 can only be interpreted tentatively. The numbers of mutable units per nucleus at 37° and 22° do not differ significantly from 1·44, so if the replication order were randomized in the population, these results would be consistent with one mutable unit per basic (non-replicating) chromosome. This would imply that both strands are involved in the primary radiation damage or that damage to single strands is afterwards either 'lost' or extended to involve the complementary strand. If, on the other hand, the replication order were fixed, our observations would be consistent with entirely double-stranded mutational events if the *try* gene were 50 ± 20 per cent of the way along the replication order. If the gene were nearer the beginning of the order a proportion of events might be confined to one strand only, but it could not exceed 50 ± 20 per cent of the total. One other possibility cannot be ruled out, namely, that only one of the two DNA strands carries transmissible information, both new strands being coded directly or indirectly from this.

There appear to be two plausible explanations of the difference between the numbers of mutable units per nucleus at 16° and at the higher temperatures. In the first place there may be repair mechanisms which are more effective at 16° than at 37° and which are more efficient for the elimination of damage from double-strand events than from single-strand ones. In the second place, DNA synthesis may occupy only part of the mitotic cycle at low temperatures[18] instead of virtually the whole cycle as at 37° (ref. 19), the remainder being a rest period corresponding to that termed G_2 in higher organisms. One can readily derive expressions for the expected number of mutable units per nucleus in terms of the time γ spent in G_2, the generation time τ and the growth rate μ ($= \ln 2/\tau$). If one assumes that a completed chromosome pair is only microscopically resolvable into two nuclei at the commencement of the next round of replication, then with a randomized replication order among the population, the average number of mutable units per nucleus is $2\,\tau(1-\exp\overline{\mu\gamma-\tau})/(\tau-\gamma)\ln 2$ for mutations which involve both strands and twice this quantity for single-stranded mutations. When the replication order is fixed and the gene involved is replicated at time t after the beginning of the cycle the corresponding expression is $2\exp(-\mu t)$. It can be shown that our results are consistent with a random replication order, almost entirely two-stranded mutational events and γ/τ (that is, relative duration of G_2) increasing from almost zero at 37° to at least 0·5 at 16°. If, on the other hand, one assumes a fixed replication order, less precision in interpretation is possible. One can only conclude that between 37° and 16° there is a substantial increase in the proportion of single-stranded events or an appreciable decrease in t/τ reflecting a rise in γ/τ.

The observed segregation patterns at the different temperatures have led us to the following broad conclusions. At 37° one basic (non-replicating) nucleus contains one unit mutable by X- or γ-rays. The larger average number of mutable units per nucleus at 16° implies that approximately half the mutational events are confined to one strand only or alternatively that there is a G_2 non-DNA-synthesizing period in the cell-cycle lasting about half a generation time.

DIFFERENCES IN THE CHARACTER OF C_6 TO C_9 HYDROCARBONS FROM GASEOUS METHANE IN LOW-FREQUENCY ELECTRIC DISCHARGES

By DR. CYRIL PONNAMPERUMA and FRITZ WOELLER

Exobiology Division, National Aeronautics and Space Administration, Ames Research Center,
Moffett Field, California

IN the study of the chemistry of primitive earth and Jovian atmospheres[1,2], there is considerable interest in the more complex products that may be formed from methane by electric discharges. There is an extensive literature on the reaction kinetics of methane in electric discharges[3,4]. A great amount of work has centred around such factors as power yields, pressure, cell design and presence of hydrogen. Few statements can be found linking these phenomena with possible pathways in primordial chemistry.

In the work recorded here the actions of several arc and semi-corona discharges on gaseous methane were studied.

Analysis by gas chromatography and mass spectrometry revealed a significant difference in the type of compounds formed in the two kinds of discharge. An attempt was made to find an explanation for the observed behaviour.

For a source of energy we used a Gardner luminous tube transformer (60 c/s, 120 V input; 15 kV/18 m.amp output; Cat. No. 1518). The two open ends of the secondary were connected to the discharge cell system, and the voltage was regulated by connecting the primary to a Variac autotransformer (General Radio Co. Type *W5LMT3*). Output currents were monitored by a 0–25-m.amp Simpson meter in one branch of the secondary. Voltages were measured with an Electrostatic kilovoltmeter (model *ESD*, Sensitive Research Instrument Corp., New Rochelle, New York). In cases where the 6-kV range would have been exceeded, the voltage was determined as the sum of voltages across three 22 megohm resistors in series. The current through the discharge cell was measured by the voltage drop across a resistor in series with the cell, and this resistor also functioned as a load to limit the current as desired, by using a value between 0·1 and 10 megohms. In two of the experiments described here, we used a pulsed arc which was automatically fired for 3 out of every 30 sec with the help of a Dual-Trol timer (Industrial Timer Corp., Parsippany, New Jersey). The discharge cell in each case was a 1,000-ml. round flask to which the respective cell heads with their electrode assemblies were attached by wide taper joints.

The semi-corona cell head consisted of a 'Pyrex' tube 100 mm in length, of internal diameter 30 mm with walls 2 mm thick. The inside electrode was made of 6-mm stainless steel tubing extended concentrically throughout the whole length of the 'Pyrex' cylinder. The glass tube was wrapped on the outside with a metal foil which covered 60 mm length in the middle section.

The arc assembly was a short cylinder into which two gold wires, 1 mm in diameter, were inserted. The electrodes were mounted through taper joints. Carbon deposited on the electrodes during the experiment could thus be shaken off by rotating the electrodes. The arc gap was maintained at approximately 10 mm.

The starting material was C.P. methane (99 per cent). At the end of each experiment, we isolated that portion of the cell contents which has more than 1 mm of pressure at −160°, and analysed it for the hydrogen–methane ratio using a G.E.C. 21-103 *C* mass spectrometer. After reading the pressure of the remainder, we transferred all those materials which could be distilled and condensed at 40μ mercury and −78° into a capillary cold finger. The volumes of these products were measured by the microsyringe used to transfer them to an Aerograph *A* 90-*P* gas chromatograph. A 0·25-in. column, 12 ft. long, packed with 10 per cent 'Octoil-*S*' on 60–80 mesh 'Chromosorb-*W*' was used. With helium at 40 ml./min, the absolute retention times were: benzene, 6 min; and toluene, 10 min. This column is similar to 'Apiezon' types, separating hydrocarbons by their boiling points. Fractions collected at −78° were examined in the mass spectrometer.

The data from seven experiments are shown in Table 1. Since the pulsed arc was operated only 10 per cent of the time, the numbers in line 3 give the net hours of current flow. The next line is intended to give a rough guide to the amount of energy consumed in the whole experiment. The apparent electrode voltage and V-amp-h reported for the semi-corona are probably too high, since the voltage has to be divided between the drop across the glass wall and that over the gas space, respectively.

Voltages and currents did not change by more than 30 per cent throughout any of the experiments, and we are listing the averages.

We have tabulated under "% loss of CH_4/h" (Table 1) the percentage of starting material consumed, divided by the number of hours. The volume of distillate reported as microlitres is intended as an illustration of the amount of material actually recovered in each experiment. In all cases the percentage composition of products was independent of the duration of the experiment.

Table 1

	Arc high continuous	Arc high pulsed		Arc low continuous		Semi-corona continuous	
Electrode voltage	2,150	850	1,450	1,275	2,260	8,900	9,425

$C_{(s)}$	†	*	*	*	*	—	—
Non-volatiles	†	—	*	*	*	†	*

Note: $C_{(s)}$ and non-volatiles: *, deposit; †, considerable deposit.

In the high-intensity arc the distillate (at 40μ and −78° C) was a clear-yellow fluid which gave chromatograms of well-spaced peaks. On the basis of the peak height, benzene was most abundant. Next in order of magnitude was toluene. A third compound the mass spectrum of which shows a sharp termination at about 106 (C_8H_{10}) corresponds to a boiling point of about 135°, and the fourth suggests a parent mass of about 104 (C_8H_8), and an approximate boiling point of 155°. The mass spectra of both these materials have been obtained, but we have not been able to characterize them using published mass spectral data.

The semi-corona cell yielded a colourless distillate the gas chromatogram of which was poorly resolved. In Fig. 1 this chromatogram (low) has been superimposed on that from the high-intensity arc (high). A significant feature of this trace was the virtual absence of any peaks where benzene and toluene should have appeared. We have obtained a somewhat better resolution at lower column temperature and flow-rate and identified some prominent peaks by mass spectrometry as follows: 2,2-dimethylbutane; 2-methylpentane; 3-methylpentane; 2,4-dimethylhexane; 3,4-dimethylhexane.

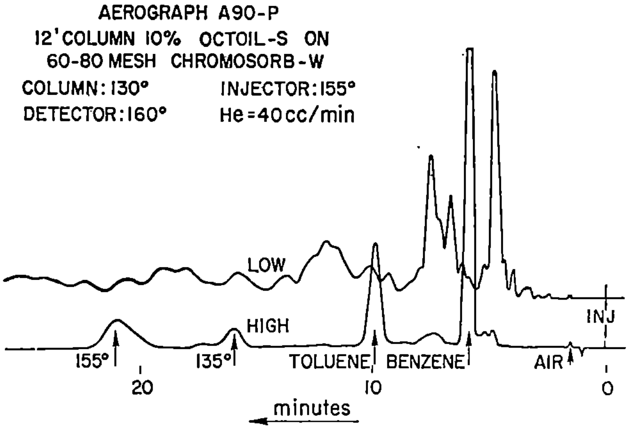

Fig. 1. Gas chromatograms of products from low intensity (semi-corona) and high-intensity (spark-discharge) cells

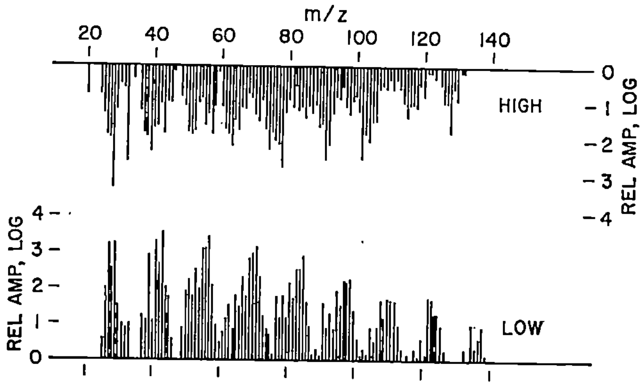

Fig. 2. Portions of composite mass spectra of products from low-intensity (semi-corona) and high-intensity (spark-discharge) cells. The ordinates represent logarithms of relative amplitudes

The low-intensity arc produced a mixture, the chromatogram of which was similar to that of the semi-corona. But, in this case, benzene and toluene were found present in small quantities (Table 1). In Fig. 2, the composite mass spectra of the high arc and of semi-corona products are contrasted to illustrate the differences in the products from the two types of discharge.

The results presented here show that the character of compounds in the range of interest appears to be determined by the type of discharge more than by any other factor. Variations in the duration of the current flow or in the cell dead volume did not at all affect the qualitative results. There is some indication that, at higher initial pressure, the relative yields of C_6 to C_9 material will tend to be higher because these materials have a better chance to condense away from the warm electrode region.

Neither discharge cell showed any gross rise in temperature under air cooling. Further, pulsing the arc brought no departure from the exclusive production of aromatics, while reducing the current did. Metal catalysis due to the gold wires or the stainless steel centre electrode is improbable, because all electrodes were soon covered with carbon deposits. In either case the possible catalytic action of carbon is not excluded.

In an attempt to explain our observations, we may consider that the arc has two primary features which distinguish it from the glow or corona discharge. One is the higher electron temperature, and the other the higher current density of the arc[5]. By inference, we also assume that the local gas temperature in the arc is higher, and that this might result in a depletion of target species in the arc zone. Since a reduction in arc current does not change the current density[6], the results of the low-intensity arc experiments suggest that here the gas temperature is lower than in the case of the high arc. Although there is a tendency toward current localization in the semi-corona after it has been operated for a brief time in this instance, the gas temperature gradient is probably far more moderate.

As it has been suggested that both the spark and the corona-type discharges could have occurred under primitive Earth conditions[7], these findings throw some light on the pathways of formation of aromatic and saturated carbon compounds under abiogenic conditions. In applying our results to the planet Jupiter, it is also conceivable that there is a correlation between the type of hydrocarbon molecule or radical appearing in its atmosphere and the form of the observed energy outbursts[8].

A TECHNIQUE FOR MINIMIZING THE EFFECTS OF ATMOSPHERIC DISTURBANCE ON PHOTOGRAPHIC TELESCOPES

By R. L. GREGORY
Psychological Laboratory, University of Cambridge

IT is well known that images in astronomical telescopes are shifted and degenerated by atmospheric disturbance. This becomes extremely important with large apertures and high magnifications: the disturbances prevent the detailed photographs which would be expected from the theoretical resolving power of large instruments. The disturbances take several forms: (1) The image may be shifted as a whole, in any direction, with varying frequency and amplitude. (2) Parts of the image may move in different directions simultaneously. (3) The image may be degenerated, especially with large aperture instruments, when the effective wave-length of the disturbance is less than the diameter of the objective. This produces a 'milkiness' of the image. This is quite different from the effect of shift when seen visually, though it may appear similar in a long-exposure photograph when the shifts produce blurring of contours and loss of fine detail.

It seems that visual observation can be preferable to photographic recording in lunar and planetary work, because the effects of the shifts of images can to some extent be avoided by visually sampling those moments when the agitation of the images is least marked. The purpose of the technique described here is to enable photographic telescopes to select moments of quiescence to build up a correctly exposed photograph.

It is clear from the kinds of disturbances encountered that any attempt to compensate the disturbances by introducing equal and opposite movements of the image on the plate will be unsatisfactory, when movements can occur in several directions in different parts of the image. Further, to get a servo-system to perform this task it would be necessary to feed it with information of the direction and velocity of the shifts, which is extremely difficult, while the servo itself would be subject to some over-shoot and tremor.

The technique under investigation is to take, first of all, a long-exposure photograph of the (atmospherically disturbed) image. The resulting photograph is statistically correct, in the sense that the major features will fall near the centre of intensity gradients produced by the random disturbance of the image. But, although the position of the contours will be nearly correct, fine detail is lost, hence the problem. This long-exposure photograph is processed, and the resulting negative is placed in its original position in the optical system, so that the

Describes the detection and separation of steroids both in clinically obtained biological fluids and tissues and in certain experimental situations.

Selected methods which give reproducible results with semi-purified extracts and which permit the separation and identification of one or more steroids in biological fluids are presented. *The methods have been chosen for rapid clinical screening.*

The discussion is limited primarily to the authors' experiences with phases, column conditioning and instrument parameters. Some biochemistry is included to clarify the methodology and **applications of GLC to steroid analysis in the normal and disease states.**
